The discoveries that the spontaneous neural activity of the cochlear nerve could be monitored as an electrical noise, with an electrode on the cochlear nerve trunk (Weinberger, N. M. *et al*., 1970; Snyder, R. L. and Schreiner, C. E., 1984; Schreiner, C. E. *et al*., 1986) and by Dolan D. F. *et al*. (1990) that electrical noise recorded from the RW was associated with the generation of spontaneous activity in the auditory nerve enabled others to exploit this finding to examine its apparent synchronicity (Cazals, Y. and Huang, Z. W., 1996). Later studies, however by McMahon C. M. and Patuzzi R. B. (2002) confirmed an original suggestion by Dolan D. F. *et al*. that the apparent synchronicity of 900 Hz is determined by the principal frequency component of the waveform of the action potentials in the type I neurons of the cochlear nerve, which is also shared by the CAP. McMahon C. M. and Patuzzi R. B. reassessed the basis of the neural noise recorded at the round window and concluded that changes in this neural noise, which Cazals Y. *et al*. (1998) had proposed as an indicator of peripheral tinnitus, was a rather ambiguous indicator because according to the findings by McMahon C. M. and Patuzzi R. B. it "can indicate changes in either the neural firing rate, as determined by stochastic quantal transmitter release or efficiency of spike initiation from excitatory post-synaptic potentials, or alternatively in the resonant properties of the primary afferent dendrites." More recently, Patuzzi and his colleagues discovered that the CAP waveform and its spectrum could be modulated either by direct current injection into scala media of the basal turn or through the RW (Brown, D. J. *et al*., 2004), or by changes to the auditory brainstem (McMahon, C. M. and Patuzzi, R. B., 2002; Sellick, P. M. *et al*., 2003). They proposed that these changes are due to the modulation of the membrane potential of the type I afferent neurons, caused by changing the extracellular potential in the case of the current injection, or via the lateral olivocochlear system of efferent neurons in the case of the brainstem manipulations (McMahon, C. M. *et al*., 2004). The measurements of neural noise at the RW membrane appear to hold considerable promise for understanding the cellular and molecular mechanisms of synaptic transmission, tinnitus, and efferent modulation of synaptic transmission by the lateral olivocochlear efferent system. Indeed measurement of neural noise at the RW has been very useful in determining the role of L-type calcium channels in mediating the release of transmitter from IHC afferent synapses (Sueta, T. *et al*., 2004). For the moment, however, the origin and properties of the noise remain to be fully understood (Patuzzi, R. B. *et al*., 2004).

3.20.8 The Nature of the Cochlear Amplifier

One of the most important challenges in understanding the workings of the cochlea concerns the identity of the amplification process itself. Shortly after Davis H. (1983) coined the phrase "cochlear amplifier," fast somatic electromotility was discovered in OHCs (Brownell, W. E. *et al*., 1985; Ashmore, J. F., 1987; Dallos, P., 1992) and the Dallos-lab (Zheng, J. *et al*., 2000) famously identified prestin, the motor molecule associated with this process in the lateral membranes of OHCs. A targeted deletion of prestin in mice (Liberman, M. C. *et al*., 2002) resulted in loss of OHC electromotility *in vitro* and a 35–60 dB loss of cochlear sensitivity *in vivo* (Cheatham, M. A. *et al*., 2004), while mechanoelectrical transduction was preserved in OHCs (Cheatham, M. A. *et al*., 2004; Jia, S. and He, D. Z., 2005). Liberman *et al*. suggested that prestin was "indeed the motor protein," and "that there is a simple and direct coupling between electromotility and cochlear amplification and that there is no need to invoke additional active processes to explain cochlear sensitivity in the mammalian ear." Detractors to the prestin theory of amplification point to fact that the hearing organs of nonmammalian vertebrates, which are without prestin, also amplify sounds and their frequency tuning is at least as good, if not better, than that of the mammalian cochlea at the same, low, frequencies (Manley, G. A. *et al*., 2001). Moreover, nonmammalian hearing organs display many of the characteristics of the mammalian cochlea and generate spontaneous emissions and distortion product otoacoustic emissions. Amplification in these organs harnesses forces provided

by the hair bundle linked to gating of the mechano-electrical transducer (MET) channels (Crawford, A. C. and Fettiplace, R., 1985; Howard, J. and Hudspeth, A. J., 1987; Martin, P. and Hudspeth, A. J., 1999). Active hair bundle movements have been detected first in non-mammalian hair cells. Here they have been correlated with two phases of MET channel adaptation (Fettiplace, R. and Ricci, A. J., 2003). Myosin-mediated slow adaptation occurs over tens of milliseconds (Gillespie, P. G. and Cyr, J. L., 2004), whereas fast adaptation occurs in tens of microseconds as the MET channel re-closes following its opening by positive deflection on the bundle. This twitch of the hair bundle is the result of a transient increase of intracellular Ca^{2+} following gating of the MET channel (Fettiplace, R. and Hackney, C. M., 2006). Fast adaptation has also been demonstrated in mammalian OHCs (Kros, C. J. *et al.*, 1992; Kennedy, H. J. *et al.*, 2003), and is associated with force generation by hair bundles (Kennedy, H. J. *et al.*, 2005). Thus both mechanisms can potentially fulfill the role of the cochlear amplifier. In nonmammalian hearing organs there is apparently no contest, and hair bundle motility is currently the only available candidate. In the cochlea there is strong, but currently not unequivocal, evidence that prestin provides amplification in the cochlea. However, does prestin act on its own (Jia, S. and He, D. Z., 2005). Does it supplement hair bundle motility (Kennedy, H. J. *et al.*, 2005)? Perhaps it mediates and modulates hair bundle motility (Chan, D. K. and Hudspeth, A. J., 2004)?

In an attempt to resolve the relative roles of hair bundle motility and somatic motility in cochlear amplification, Santos-Sacchi J. *et al.* (2006) investigated the nature of the cochlear amplifier based on the hypothesis that chloride ions interact with the intracellular domain of prestin to confer voltage sensitivity (Oliver, D. *et al.*, 2001) and that that chloride movements via the OHC lateral membrane conductance *G*metL, could serve to underlie cochlear amplification (Rybalchenko, V. and Santos-Sacchi, J., 2003). Santos-Sacchi J. *et al.* (2006) used salicylate, which competes with the putative anion binding or interaction site of prestin, to determine the resting level of chloride in OHCs. They found this to be near or below 10 mM, whereas perilymphatic levels are known to be ~120 mM. Using this observation, they explored the effects of perilymphatic chloride levels on BM amplification in the guinea-pig cochlea. Reductions in perilymphatic chloride resulted in reversible reductions in OHC electromechanical activity and cochlear amplification. They argued that changes in the extracellular chloride levels will not influence the cation-selective hair bundle MET channels process and associated fast adaptation, and that their findings lend further support to the proposal that prestin activity is dominant in underpinning the cochlear amplifier.

Chan D. K. and Hudspeth A. J. (2004; 2005) have measured hair bundle motility from IHCs in cochlear explants and mechanical responses of the organ of Corti of the explants to electrical and acoustic stimuli. Their measurements of the stiffness of the TM, BM, and hair bundles and modeling studies support the notion that "active forces generated by hair bundles can amplify movements of the basilar membrane."

From their studies and earlier measurements, they attribute the hair bundles' stiffness largely to the tip links, which are ideally located as bi-directional mechanoelectrical, electromechanical, transducers of energy between the TM and hair bundle. "An active process based on the transduction channels themselves, or on the myosin motors that anchor the channels to the stereociliary actin cores, would therefore be able to drive movement of the cochlear partition and contribute to active amplification." Thus Hudspeth and Chan seem to concur with Kennedy H. J. *et al.* (2005) that prestin and hair bundle motility share the role of cochlea amplifier. This is all well and good if both mechanisms work in synergy. Perhaps they do not. Perhaps one acts to amplify, and the other to compress, the cochlea's responses to the enormous dynamic range of stimuli it can cope with. At this moment, there is also no unequivocal evidence from measurements made *in vivo* that isolate a role for hair bundle motility in cochlear amplification in the mammalian cochlea. Otoacoustic emissions, that are distortion products and can signature cochlea amplification, have been recorded from mice with a targeted deletion of prestin where they have been tentatively attributed to hair bundle motility (Liberman, M. C. *et al.*, 2004), although otherwise these mice are profoundly insensitive (Liberman, M. C. *et al.*, 2002; Cheatham, M. A. *et al.*, 2004).

Glossary

acoustic click Sound stimulus – a brief transient – that is composed of most audible frequencies, produced by exciting an earphone with a brief direct-current pulse (e.g., 100 μs duration for a bandwidth of nearly 10 kHz).

auditory brainstem response (ABR) Electrical potential derived via computer averaging to extract a sensory (auditory) signal evoked by the applied (sound) stimulus, generated by the auditory nerve and brainstem auditory pathways (namely, pontine level).

cochlear mechanics Sum of hydromechanical events of the cochlea (auditory portion of the inner ear) involved in the transduction of sound.

frequency-following response (FFR) Variation of the auditory brainstem response elicited by tone bursts and whose waveform follows the waveform of the stimulus.

frequency-specific Characteristic of sound stimuli whose energy is largely concentrated around a particular frequency.

latency Time delay between the onset of a stimulus and the onset of a given wave of a stimulus-evoked potential.

masking A stimulus used to obscure/eliminate a sensory response evoked by another (probe or target) stimulus.

place encoding mechanism Effect of cochlear mechanics such that the displacement maxima occur at a place specific to the stimulus frequency and wherein high-frequency maxima tend to occur toward the base, and low-frequency maxima toward the apex.

threshold In sensory physiology and psychology, the concept that there is a stimulus magnitude that is just adequate to reliably excite a response (e.g., action potential, sensory-evoked potentials like the auditory brainstem response, behavioral response such as pushing a button, etc.).

tone burst Sinusoidal pulse, formed by abruptly turning on and off a sine wave.

traveling wave The wavelike motion peculiar to the cochlea by which sound energy is efficiently coupled to the basilar membrane and travels along this structure from the cochlear base toward the apex, reaching a maximum at a place according to the sound's frequency.

vertex (Cz) Location on the scalp at the top of the head, frequently used as a recording site for sensory-evoked potentials like the auditory brainstem response.

whole-nerve action potential (AP) Compound action potential of the auditory (VIII cranial) nerve in response to sound stimulation, thereby a population response of first-order auditory neurons.

The auditory brainstem response (ABR) is a compound neural potential recorded from the scalp. Obtaining the ABR requires computer signal averaging to extract this $0.5 = \mu V$ signal from background electrical noise. The ABR comprises a series of waves falling within the first approximately 10 ms of bioelectrically generated response to the onset of sound (Figure 1(a)), representing in turn the initial stages of activation of the auditory nervous system. This signal has found extensive clinical use via four major applications (see reviews by Hall, III, J. W., 1991; Durrant, J. D. and Ferraro, J. A., 1999; Goldstein, R. and Aldrich, W. M., 1999). The first is neurodiagnostic testing wherein the waveform and/or timing of the

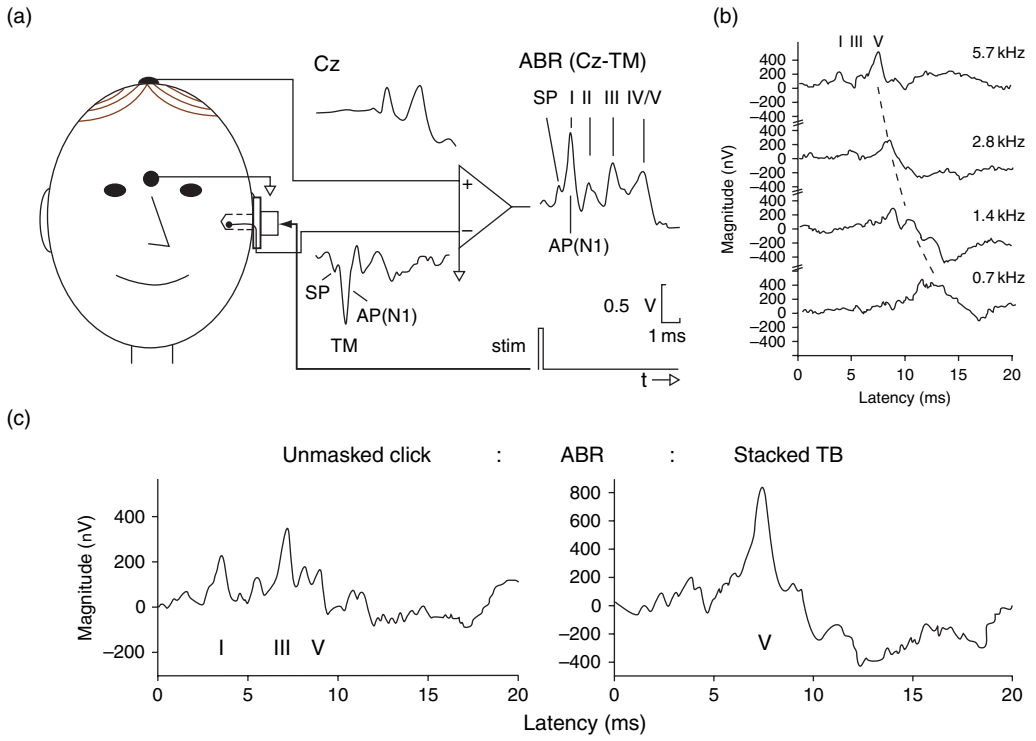

Figure 1 (a) The auditory brainstem response (ABR) is recorded between electrodes placed on or near the vertex (Cz) of the head and the ear (earlobe, mastoid, ear canal, or deeper). Enhancement of the diminutive wave I recorded at the scalp's surface can be accomplished by combining ABR recording with electrocochleography (ECochG), using an electrode deep in the ear canal or on the tympanic membrane (TM). Here, even the cochlear summating potential is detected, along with a more prominent N1 component of the whole-nerve action potential (AP). A third electrode, at nasion, completes the electrode montage for electrical grounding and safety of the subject. The stimulus (stim) derives from exciting the earphone with a brief direct-current pulse, delivering energy essentially at all frequencies shaped by the transducer's frequency response. The ABR component waves are labeled by Roman numerals (according to Jewett, D. L. and Williston, J. S., 1971). (b) A strictly surface recording method (vertex to mastoid) was used to record ABRs in response to sinusoidal pulses of various frequencies, as indicated. The dashed line traces the latency shift associated with effectively shifting the place of stimulation from near the cochlear base (high frequencies) to near the apex (low frequencies). (c) Tone-burst responses were aligned according to wave-V latency and summated to produce the stacked ABR (panel: stacked TB (tone burst)), reducing the untoward effects of traveling-wave dispersion (panel b) and dramatically improving ABR magnitude compared to that elicited by the broadband, unfiltered click (panel: unmarked click).

ABR waves are evaluated to detect neural blockage from space-occupying lesions, demyelinating diseases, etc. The second is newborn hearing screening which takes advantage of the strong correlation between ABR detection levels and behavioral hearing thresholds, plus the ability to record ABRs in sleeping/sedated patients, even premature infants. The third application is hearing threshold estimation which combines the advantages of ABR testing for newborn screening with the use of frequency-specific stimuli to estimate the audiogram (the pattern of hearing loss across frequency) in young pediatric, mentally handicapped, and other difficult-to-test subjects. The last application, intraoperative monitoring, capitalizes on most of the features above to provide a test keenly sensitive to conditions adverse to neural conduction in peripheral nerve and pontine-brainstem structures; monitoring the status of the ABR can help to minimize damage from neurosurgical procedures.

It may be asked, "What is such a topic as the ABR doing as follow-up to a chapter on cochlear function?" The short answer is that the ABR is actually a misnomer; the first two waves of the ABR derive from responses of the VIII nerve. Generally recorded between metal electrodes placed near the top of the head (vertex) and the stimulated ear (Figure 1(a)), the first barrage of electrical activity registered is nothing more than the N1 component of the whole-nerve action potential (AP). Indeed, using an

electrode deep in the ear canal or on the tympanic membrane enhances the AP (Figure 1(a)) and may reveal stimulus-related cochlear potentials, such as the summating potential (SP) – a method known as electrocochleography (ECochG). ECochG can also be performed using a needle electrode to penetrate the tympanic membrane, resting on the promontory (lateral wall of the cochlea, near the niche of the round window). The other potential that can be recorded is the cochlear microphonic. The SP and AP have been found useful for the differential diagnosis of Meniere's disease, characterized by a condition known as cochlear hydrops. In hydrops cases, the SP tends to be exaggerated in absolute magnitude or relative to the AP, perhaps reflecting asymmetrical mechanical biasing of the cochlear partition and/or biochemical effects due to this condition. Figure 1(a) illustrates another application of ECochG, combined with ABR recording (Durrant, J. D., 1986), to enhance wave I of the ABR, as this wave may be easily obscured by peripheral hearing loss. After the VIII nerve traverses the highly dense and electrically insulating temporal bone (specifically, the petrous pyramid), a second electrical wave develops as the nerve exits in the cerebellopontine angle, en route to the brainstem (Moller, A. R., 1994; Martin, W. H. *et al.*, 1995). This too is a manifestation of activity of the VIII nerve, that is the first-order neurons of the auditory pathway. Consequently, not until the third wave is the ABR truly a brainstem response; this and later waves are registered more prominently by the vertex (Cz) electrode (Figure 1(a)).

The longer and less obvious answer, regarding relevance of the ABR here, is that its nuances are strongly determined in the auditory periphery, despite the fact that waves III–V (Figure 1(a)) are generated in the pons between the dorsal–ventral cochlear nucleus complex and the inferior colliculus (Scherg, M. and von Cramon, D., 1985; Moore, J. K., 1987; Durrant, J. D. *et al.*, 1994). The representation of stimulus onset in the discharge patterns of auditory neurons is quite robust regardless of neuron type (Kiang, N. Y. S., 1975). Thus, the onset of the stimulus excites a high spike-discharge rate such that this feature of the primary-neural discharge pattern is prevalent throughout the auditory pathways. The several waves of the ABR are readily attributable to the sequential connectivity of the nerve and brainstem pathways which provide a combination of axonal (propagation) and synaptic delays at each major nucleus (Scherg, M. and von Cramon, D., 1985; Moore, J. K., 1987). Consequently, the activity at each level of the pathway will be passed on to the next, as in a relay race. The result is a multiphasic compound neural response of several milliseconds duration.

As conventionally tested, a simple wideband stimulus, called the acoustic click, is used to elicit the ABR. As such, the ABR may be considered as the impulse response of the combined VIII-nerve and brainstem systems. The input sound approximates an ideal impulse (a very brief transient). The click is created by exciting the earphone transducer with a brief direct-current pulse, typically 100 μs in duration (Figure 1(a)), providing equal power at all frequencies up to nearly 10 000 Hz (see Durrant, J. D. and Lovrinic, J. H., 1995 for review of underlying principles). Consequently, the output signal (waves of the ABR) is expected to reflect activity representing a broad frequency range, if, in fact, the frequency content of the input stimulus was well encoded by the hearing organ. The preceding chapter has established that, indeed, it should have been, but through the rather special transform effected by traveling-wave mechanics. The brainstem thus sees the outside world through the VIII nerve, which, in turn, sees the world through an array of variably tuned narrow-band filters produced by the place-encoding mechanism of the basilar membrane and the outer hair cells. Recall that, by this mechanism, the basilar membrane is not excited all at once, rather the traveling-wave motion is propagated with finite speed from the base toward the apex. The result is that the different best-frequency regions are excited sequentially, progressing from high- (basal) to low-frequency (apical) places.

Due to cochlear mechanics, the AP reflects activity at most audible frequencies in response to the simple (unfiltered) click, yet not instantaneously. Consequently, the click waveform (or its frequency content) is not obvious in the recorded signal. In other words, the AP (ABR wave I) does not mimic the input signal. True, it still is brief, roughly 1 ms in duration and thus is itself a transient. In contrast, it would take several milliseconds of activity to represent the entire cochlear response, again due to traveling-wave propagation. In VIII-nerve activity alone this would outlast the entire click-evoked ABR! So where did the rest of the activity go? Well, this same encoding mechanism, by virtue of the cochlear propagation delay, as well as filtering properties of the cochlear hydromechanics, causes phase dispersion. Activity from the base, where the traveling-wave velocity is high and the propagation delay

(and thus phase dispersion) is minimum, dominates the recorded response, yielding the robust but temporally compact wave observed. In contrast, activity from more apical regions tends to cancel out. Still, an appropriate masking technique (use of interfering noise of different cut-off frequencies) or frequency-specific stimuli (use of sinusoidal pulses (tone bursts)) can be used to isolate more apical places of excitation.

The same approach can be taken with the entire ABR (which suffers the same fate as the AP, accounting for its own compactness), as shown in Figure 1(b). Note the shifting latency (delay from the start of the stimulus), namely increasing latency as frequency of the stimulus decreases. Recombining the frequency- or place-specific responses, while compensating for the traveling-wave delays (stacked TB ABR in Figure 1(c)), produces a substantially greater magnitude of response (Philibert, B. *et al.*, 2003). Interestingly, stimulus intensity also has a dramatic and related effect (Figure 2(a)). As stimulus intensity decreases, not only does the response magnitude decrease (as expected), but the peaks of the earlier/smaller waves disappear, and the waves occur at progressively longer latencies. This results from a combination of effects, including a basic neural effect – the characteristic increase of latency with decreasing stimulus intensity (Kiang, N. Y. S., 1965), and a cochlear mechanical effect – progressively fewer neurons excited on the tails of their turning curves (Ozdamar, O. and Dallos, P., 1976). The latency-intensity tradeoff is the hallmark of auditory-evoked responses. Given such pervasive influence of cochlear mechanics on the ABR, it seems likely that traveling-wave velocity could be estimated using ABR latency measures, as indeed is the case (e.g., see Donaldson, G. S. and Ruth, R. A., 1993). This entirely noninvasive clinical tool thus permits the examination of cochlear function in intact humans and other animals.

With all this attention to place-frequency encoding, what about time synchrony? In fact, a high degree of synchrony of neural discharge is essential

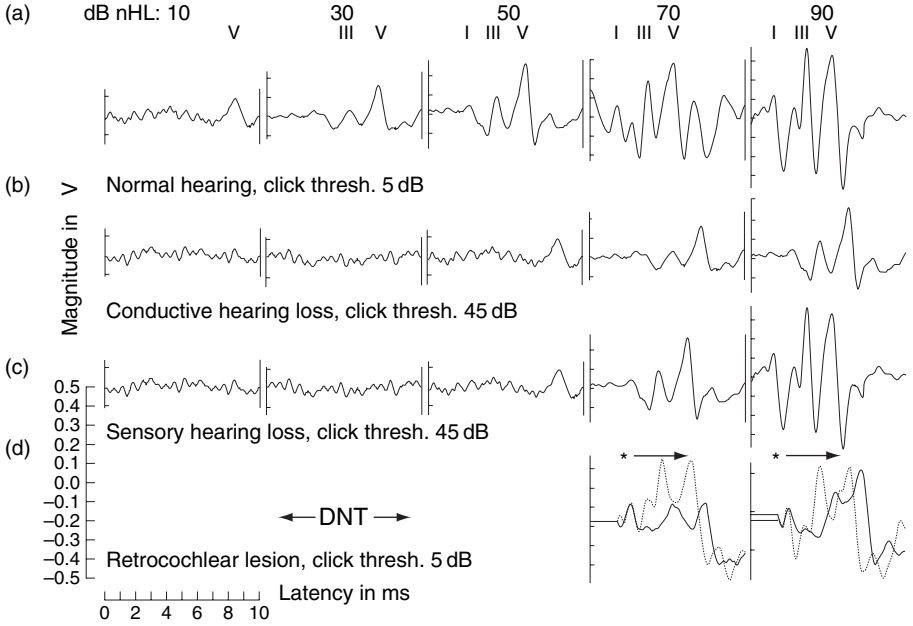

Figure 2 Illustration of typical effects of level of the acoustic-click stimulus (a), peripheral auditory pathology (b, c), and retrocochlear lesion on the auditory brainstem response (ABR). a, Normal ABR recorded at click hearing levels indicated: just at/above hearing threshold of the acoustic click stimulus, and several levels above, yielding at 70 and 90 dB hearing level full complements of waves. b, Simulated flat conductive loss, typical of middle-ear disease, leading merely to simple attenuation of the stimulus, i.e., the 90 dB response corresponds to the 70 dB, and the detection level of the response is elevated. c, Simulated high-frequency sensory loss, yielding similar effects to the conductive loss at low levels but by 90 dB, in this case, an essentially normal amount of activity is recruited due, in part, to basalward spread of excitation. d, Actual responses from a case of acoustic tumor which, in this case, had virtually no adverse effects on the usual tests of hearing, yet causing a clear delay in neural conduction in the VIII nerve (indicated by prolongation of the I–III∗ interpeak interval). DNT, did not test; nHL, normal hearing level.

for a good ABR. Stimuli with relatively long rise times yield poor responses (Hecox, K. *et al.*, 1976). The click is highly effective, not only because of its broad bandwidth, but also its abruptness. Subtle timing cues, in fact, are readily evident in the ABR, for example, the slight time difference between condensation (C) and rarefaction (R) polarity stimuli – stimuli initiated with a push versus a pull on the eardrum. The result in the average subject is that there is a subtle, yet measurable, difference in waveform and latency between the C- and R-evoked ABRs (see Durrant, J. D. and Ferraro, J. A., 1999). This follows from the fact that the excitatory phase of stimulation in the cochlea is basilar membrane movement (displacement and velocity) going from scala tympani to the scala vestibuli (Dallos, P. and Durrant, J. D., 1972); this motion corresponds to R.

Still more compelling is the extent to which phase synchrony can be expressed in the ABR under appropriate recording conditions. Returning to Figure 1, inspection of the ABR reveals a pseudosinusoidal waveform. It may not be too surprising, then, that short sinusoidal pulses can be used to drive this feature to produce a frequency-following response (FFR) that more-or-less mimics the stimulus waveform (e.g., see Ananthanarayan, A. K. and Durrant, J. D., 1992). The FFR responses are most robust in the mid-frequency range of hearing, roughly 500–2000 Hz, the upper range being consistent with the upper limit of the most efficient phase locking of single auditory neurons (the lower limit perhaps reflects the general deterioration of the ABR at low frequencies, as low-frequency stimuli have inherently slower onsets. In general, the ABR is not quite as robust/distinctive when elicited below 1000 Hz; e.g., see Kiang, N. Y. S., 1965; Joris, P. X. *et al.*, 1994a; 1994b). This temporal synchrony is robust enough that the FFR can be used to study encoding of complex stimuli, most notably vowels of speech (Krishnan, A., 2002). So complete is this reflection of cochlear events, that yet another manifestation of cochlear function, that is, nonlinearity (e.g., intermodulation distortion products), is also expressed in FFR activity (Pandya, P. K. and Krishnan, A., 2004).

To outline this of clinical correlation, a few examples of applications and related concepts will be worthwhile. The most basic manifestation of cochlear function is hearing sensitivity. While it certainly takes the rest of the auditory pathways to provide the sense of hearing and related conscious/voluntary responses, as sampled via conventional (behavioral) audiometry, it is well established that the limits of hearing sensitivity are determined by the peripheral auditory system. It was noted earlier that a common application of the ABR is found in newborn hearing screening and hearing threshold estimation in young children and others incapable of participating in the standard (behavioral) clinical test. This application enjoys broad utility, providing reliable screening for hearing impairment and threshold estimation often to within an accuracy of 10 dB, as illustrated in Figure 2(a). Such results, in practice, are usually obtained while the subject is asleep naturally or under sedation or general anesthesia. This is possible because the generators of the ABR are below the inferior colliculus and strongly driven by the peripheral nerve, as revealed above. In many pediatric patients, a common problem of hearing is fluid in the middle ear which attenuates sound delivered to the inner ear and causes changes in the ABR (see Figure 2(b)). Hearing loss in the population at large, however, is most often caused by loss of hair-cell function, frequently limited to the higher frequencies. This also causes deterioration in the ABR. However, moderate or less severe losses may be overcome with increasing stimulus intensity due to basalward spread of excitation from the traveling wave, which may finally overcome the impaired thresholds of more basal or high-frequency neurons (Figure 2(c)). Consequently, the ABR may be used to explore/define such losses and the nuances of their effects. The latency-intensity relationship, specifically, can help predict hearing loss type (conductive versus sensory) and degree. At the same time, such peripheral effects must be fully appreciated before retrocochlear neural influences can be confidently deduced.

This brings the discussion to another major application of ABR testing, that of differential diagnosis (see Durrant, J. D. and Ferraro, J. A., 1999, for review). The effects of a common space-occupying retrocochlear lesion (the acoustic tumor) also is illustrated in Figure 2. In this case, the compression of the VIII nerve by the tumor appears not to significantly affect hearing sensitivity, at least not as clinically tested, yet the lesion has clear impact on the ABR. The delay between waves I and III is consistent with the site of lesion, i.e., blockage of VIII-nerve conduction. Over the past decade, the clinical importance of the ABR for detection of such tumors has diminished with advancements in imaging. However, Don M. *et al.* (1997) have shown that, by using an approach similar to that represented in Figures 1(b) and 1(c) (i.e., stacked ABR analysis),

the ABR can be enhanced, providing a more thorough test of VIII-nerve function, that is, not merely the higher-frequency response elicited via the unfiltered click (Don, M. *et al*., 1997; Philibert, B. *et al*., 2003). Interestingly, the basic stimulus-analysis paradigm of the stacked-ABR test was developed over four decades ago for the purpose of breaking down the click-evoked AP into its (equivalent) component frequency bands (Teas, D. C. *et al*., 1962). The method represents the results of the much more tedious and invasive analysis of single-unit-response measurement along the nerve trunk well (Kiang, N. Y. S., 1975), again reflecting propagation events along the cochlear partition. Lastly, the acoustic-tumor example also demonstrates the basis for use of the ABR in intraoperative monitoring, in this case the possible compression of the VIII-nerve or more central fiber tracts during neurosurgery.

In summary, cochlear events are strongly manifested in, and determine many characteristics of, the ABR. While a powerful and sensitive clinical tool for investigating or ruling out retrocochlear pathology and objective hearing screening, ABR recording is an equally valuable investigative tool in the evaluation of peripheral auditory sensorineural events.

Glossary

active zone (AZ) The area where synaptic vesicles fuse with the presynaptic membrane. The AZ is juxtaposed to the postsynaptic terminal across the synaptic cleft.

afferent The flow of signals from the periphery toward the central nervous system (CNS).

auditory nerve fiber (ANF) The axon of an auditory afferent neuron that projects to the brainstem in the vestibulocochlear (eighth cranial) nerve. In mammals, ANFs have cell bodies in the spiral ganglion.

characteristic frequency (CF) The frequency of maximum sensitivity to sound.

cytomatrix at the active zone (CAZ) The cytoskeletal meshwork comprised of multidomain proteins that aggregate through specific protein–protein and protein–lipid interactions. The CAZ creates a scaffold upon which the presynaptic machinery is assembled.

hair cells The sensory receptors of the auditory system and related sense organs of the ear and lateral line of vertebrate animals.

inner hair cell (IHC) One of the highly innervated hair cells in the mammalian ear that are primarily responsible for the perception of sound. They are located in a single row near the modiolar (inner) edge of the organ of Corti.

root mean square (RMS) A type of average computed by first squaring a set of values, then computing the mean of the squared values, then taking the square root of the mean. The RMS average deviation of N samples from their mean is $\sqrt{(N-1)}$ times the standard error of the mean.

sound pressure level (SPL) The RMS pressure change during a sound, expressed on the logarithmic decibel (dB) scale, measured in the vicinity of the listener during a specified time period.

spiral ganglion The cell bodies of the afferent neurons that innervate the organ of Corti; housed in the bony spiral lamina of the mammalian cochlea.

spontaneous rate (SR) Frequency of spikes in an auditory nerve fiber in the absence of an applied sound stimulus.

synaptic body or ribbon (SB) The most obvious presynaptic structure at hair cell afferent synapses, and the subject of many carefully designed experiments to reveal its function(s). There is general agreement that the SB serves an important purpose, which is not presently known. It harbors synaptic vesicles attached to it via fine filaments that are thought to either facilitate or impede the movement of vesicles along its surface.

synaptic vesicle (SV) Spherical lipid bilayer that contains neurotransmitter.

synaptic vesicle cycle The recurrent processes by which SVs are continuously created, used and recreated. Exocytosis of the neurotransmitter is triggered by calcium and involves fusion of the SV membrane with the plasmalemma and/or the formation of a transient aqueous connection between the SV and the extracellular space. After exocytosis, SVs are reformed, refilled, and reenter the exocytic pathway.

threshold The SPL needed to produce a criterion response. Defined in this way, threshold is a measure of sensitivity to sound: low threshold means high sensitivity. Sensitivity is usually expressed in units of response/stimulus, but in auditory physiology threshold is traditionally defined in units of stimulus only, omitting explicit reference to the response criterion used in a particular experiment.

3.22.1 Introduction

We will begin with an overview of the hair cell afferent synapse and related structures, with a focus on mammalian inner hair cells (IHCs) and spiral ganglion neurons. Our review will then turn to electrophysiological studies and discussions of the specializations that may endow these first auditory synapses with their ability to maintain fast and reliable, information-rich signaling to the brain. Readers unfamiliar with the basics of cellular neuroscience will better appreciate the unique properties of auditory afferent synapses after reviewing the properties of conventional chemical synapses described in the many excellent neuroscience textbooks (e.g., Delcomyn, F., 1998; Kandel, E. R. *et al.*, 2000; Hille, B., 2001; Nicholls, J. G. *et al.*, 2001). Additional information specific to hair cell afferent synapses can be found in recent literature reviews (Nouvian, R. *et al.*, 2006; Moser, T. *et al.*, 2006a; 2006b).

3.22.2 Afferent Neurons of Acousticolateralis Sensory Systems

The primary afferent neurons in the auditory and vestibular organs of all vertebrate species, and in related mechanosensory and electrosensory organs of the lateral line system of aquatic vertebrates are bipolar neurons that have cell bodies located in or near the ear. They extend one process peripherally to the sensory epithelium, the other centrally to the brainstem. The peripheral processes have often been called dendrites, but most are myelinated and can properly be called axons. This distinction is likely to be important for the assembly and maintenance of afferent synapses because axons and dendrites use different protein-targeting signals (Burack, M. A. *et al.*, 2000). The afferent neurons in auditory and vestibular organs have cell bodies located close to the corresponding sensory epithelium, and therefore have short peripheral axons.

Lateral line afferent neurons have long peripheral axons that extend from cell bodies in the lateral line ganglia near the ear to sensory neuromasts on the head and trunk (Dambly-Chaudiere, C. *et al.*, 2003).

3.22.2.1 Spiral Ganglion Neurons

In mammals, the cell bodies of auditory afferent neurons reside in the spiral ganglion, which parallels the inner (modiolar) edge of the organ of Corti (Figure 1(a)). Type I spiral ganglion neurons are responsive to acoustic stimulation and constitute 90–95% of cochlear nerve afferents (Spoendlin, H., 1969; Liberman, M. C., 1982). Intracellular labeling with horseradish peroxidase and subsequent histological processing revealed that they contact only the IHCs (Robertson, D., 1984). Both the peripheral and the central axons of a type I afferent neuron are myelinated and have a cluster of voltage-gated Na^+ channels (Na_v 1.6) at each node of Ranvier. Na^+ channels are also found in the unmyelinated axon segment between the postsynaptic terminal and the most distal peripheral node, suggesting that spikes may be initiated at or near the site of synaptic input (Hossain, W. A. *et al.*, 2005), as occurs in vertebrate skeletal muscle (Kandel, E. R. *et al.*, 2000). Minimizing the distance from the synapse to the spike initiation site is expected to minimize attenuation and low-pass filtering of excitatory postsynaptic potentials (EPSPs). The cell bodies of type I spiral ganglion neurons are also wrapped in a loose myelin-like sheath that may speed conduction, reduce temporal jitter, or decrease the probability of conduction failure across the cell body during high-frequency firing (Hossain, W. A. *et al.*, 2005).

In mammals, the peripheral axons of type I afferents (also known as radial fibers) remain unbranched and contact only a single IHC. Unlike most neurons, which receive synaptic inputs from hundreds or thousands of separate sites of synaptic contact (active zones; AZs), each type I afferent neuron typically receives sensory input from a single hair cell AZ (Spoendlin, H., 1969; Liberman, M. C., 1980; Spoendlin, H., 1985; Hashimoto, S. *et al.*, 1990). In other vertebrates, most auditory afferent neurons make multiple postsynaptic contacts on one or more hair cells (Lewis, E. R. *et al.*, 1982).

Each mammalian IHC provides the sole input to 5–30 type I afferent axons, which vary in number by species and hair cell position on the cochlear tonotopic axis (Kiang, N. Y. S. *et al.*, 1982; Liberman, M. C., 1982; Fuchs, P. A. *et al.*, 2003). The mammalian cochlea thus represents a case of synaptic divergence in which each IHC controls many private communication channels to the brain. The function of this unusual arrangement is only partially understood, but it is easy to speculate that the dynamic membrane potential of the hair cell contains more information than can be transmitted across one synapse and encoded in a single spike train.

Information is degraded by events that alter a signal in an unpredictable way (noise). The synaptic noise introduced by the stochastic nature of exocytosis can be reduced by having synaptic currents from many AZs converge on the spike initiation zone of one afferent axon, as occurs at the calyx synapses of vestibular hair cells (Goldberg, J. M., 1996); but the mammalian auditory system uses a different strategy in which the maximum possible separation of information channels to the brain is maintained by having each synaptic AZ control action potential generation in a separate afferent axon. If separate information channels later converge onto a single higher-order neuron in the brain stem (e.g., a globular bushy cell in the cochlear nucleus that detects coincident input), this arrangement can reduce the effects of variability in the spike conduction time from the ear to the central nervous system (CNS) and other noise sources that are downstream of the afferent synapse.

A small population of afferent axons in the mammalian cochlea (type II; Figure 1(a)) are unmyelinated (Liberman, M. C. *et al.*, 1990). Like the type I afferents, they are labeled by antibodies against Na_v 1.6 and may initiate action potentials near their distal tips (Hossain, W. A. *et al.*, 2005). These outer hair cell (OHC) afferents are thought to monitor the state of the organ of Corti, but not to contribute directly to the perception of sound, the role ascribed to the IHCs. Very little is known about the physiology of type II afferents, and they will not be considered further in this chapter.

Although the peripheral neural network in the ear is less elaborate than that of the retina and contains far fewer cell types, electron micrographs of the organ of Corti do show several additional types of synapses that could provide important functional interactions, including local feedback (Raphael, Y. and Altschuler, R. A., 2003; Sobkowicz, H. M. *et al.*, 2003). These include connections between IHCs and OHCs via afferent and efferent fibers that contact both hair cell types (Sobkowicz, H. M. *et al.*, 2004). Nothing is known about the function of these synapses in auditory signal processing. Efferent synapses are typically seen on the postsynaptic

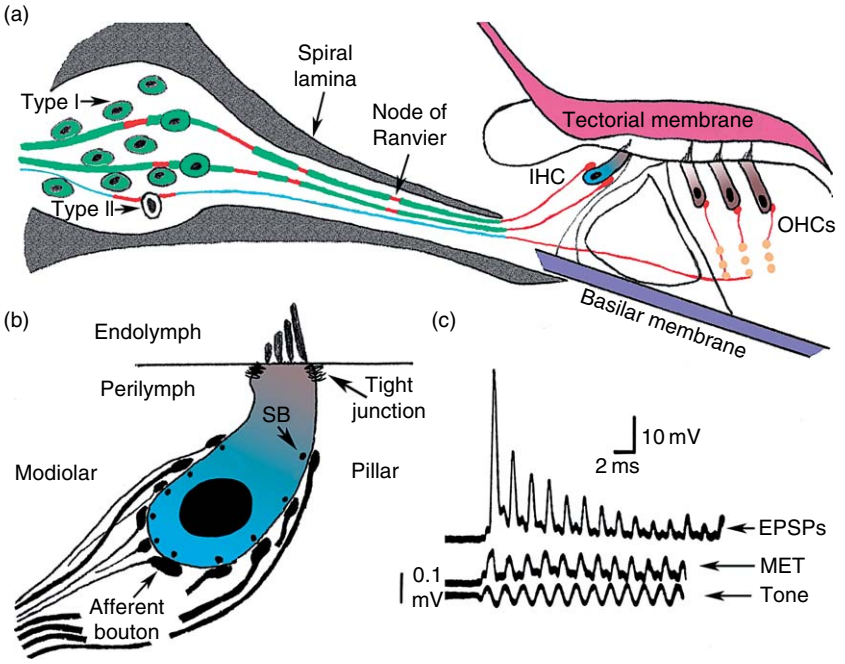

Figure 1 Auditory afferent synapses. (a) Schematic cross section through the mammalian organ of Corti, showing the bipolar cell bodies of afferent neurons (left), which each send one axon peripherally toward the hair cells and another axon centrally to the brainstem. In mammals, most afferent axons (type I) are myelinated (green), unbranched, and contact a single inner hair cell (IHC). A smaller population (type II) are unmyelinated and branch to contact several outer hair cells. A high density of voltage-gated sodium channels (Na_v 1.6, red) are located at nodes of Ranvier, on the unmyelinated distal axon segments of all afferent neurons, and at both axon hillocks of type II neurons. (b) Each IHC supplies the only input to tens of type I afferent neurons at active zones. Large-diameter afferent axons usually contact the pillar face of the IHC, whereas smaller-diameter axons contact the modiolar side. (c) Electrophysiological recording of afferent synaptic activity *in vivo*. A 200 Hz sinusoidal sound delivered to the goldfish sacculus (bottom trace) evoked an extracellular field potential (middle trace), analogous to a cochlear microphonic potential (see Chapter Hair Cell Transduction and Adaptation: Physiology and Molecular Mechanisms), that is primarily a measure of mechanoelectrical transduction (MET). The top trace is an intracellular recording from an afferent axon, in which spikes had been blocked to reveal the EPSPs, which are synchronized to the sound waveform and show strong synaptic depression. (c) Adapted from Furukawa, T. and Matsuura, S. 1978. Adaptive rundown of excitatory postsynaptic potentials at synapses between hair cells and eighth nerve fibres in the goldfish. J. Physiol. 276, 193–209, with permission from Blackwell Publishing.

terminals of mammalian type I afferents, where they may modulate synaptic transmission from the hair cell to the afferent axon. Efferent axons also make inhibitory cholinergic synapses directly onto hair cells in most vertebrate auditory and vestibular organs, including mammalian IHCs and OHCs (see Chapter Efferent System).

3.22.2.2 Auditory Nerve Fibers

The central axons of spiral ganglion neurons project to the brainstem in the eighth cranial nerve, where they are called auditory nerve fibers (ANFs). Nearly all recordings of action potentials in mammalian ANFs are presumed to be from axons of type I spiral ganglion neurons because they are larger and much more numerous than the axons of type II neurons (Liberman, M. C., 1982).

In vivo recordings from single ANFs show that nearly all fire action potentials spontaneously (i.e., in a quiet laboratory environment with no experimentally imposed stimulus). The baseline or spontaneous firing rate (SR) in some ANFs exceeds 100 spikes s^{-1}, while others fire fewer than 5 spikes s^{-1}, with no apparent correlation between a fiber's characteristic frequency (CF) and SR (Kiang, N. Y. S. *et al.*, 1965; Tsuji, J. and Liberman, M. C., 1997). CF varies with position along the tonotopic axis whereas SR has been correlated with both axon diameter and subcellular synaptic structure in the guinea-pig and cat (Liberman, M. C., 1980; Merchan-Perez, A. and Liberman, M. C., 1996; Tsuji, J. and Liberman, M. C., 1997). In these studies of afferent structure/function,

intracellular recording and labeling of individual ANFs followed by serial-section electron microscopy (EM) showed that ANFs of high SR belong to spiral ganglion neurons that have large diameter peripheral axons and contact IHCs predominantly on the pillar face (Figure 1(b)); however, this segregation of axonal diameters around the hair cell circumference was not observed in one study of the gerbil (Slepecky, N. B. *et al*., 2000). Low- and intermediate-SR fibers of the cat and guinea-pig contact the modiolar face and have synapses with larger presynaptic dense bodies (called synaptic bodies, SBs, or ribbons) and more vesicles than synapses with high-SR fibers. Because the 5–30 afferent synapses on each IHC display this range of ultrastructural characteristics and modiolar/pillar position, and because ANFs of the same CF differ in SR, it is inferred that each IHC synapses onto both high-SR fibers and intermediate-/low-SR fibers.

To quantify the strength of a sound, most experimenters report the sound pressure level (SPL), expressed on the logarithmic decibel scale (dB). Each 20 dB increase in SPL corresponds to a tenfold multiplication of root mean square (RMS) sound pressure. The zero point (0 dB) is often defined as 20 μPa, which is approximately the amplitude of a barely perceptible sound at frequencies where human hearing is most sensitive (2–5 kHz). Compared to the standard atmospheric pressure of ~100 kPa, 20 μPa amounts to a change of only about 1 part in 5 billion.

An ANF's sensitivity to sound (Figure 2) is typically measured as the SPL needed to increase its firing rate by a criterion number of spikes per second above the SR, or alternatively, to produce a criterion increase in ANF discharge synchrony with the sound stimulus (Rose, J. E. *et al*., 1967; 1971; Johnson, D. H., 1980). This measure, which is often called the fiber's threshold, depends on the response criterion, stimulus duration, and other factors that are specific to the experimental protocol (Heil, P. and Neubauer, H., 2003). The term threshold is typically used in biology to mean a stimulus level below which there is no response (e.g., the threshold for generating an action potential), and therefore implies the existence of a strong nonlinearity in the stimulus–response relation (a cut-off below which there is no response). The use of the term threshold in auditory physiology is quite different. It carries no implication of a threshold nonlinearity, only that the response has fallen below some criterion level. In fact, the initial stages of auditory processing are constructed to avoid threshold nonlinearities.

A threshold nonlinearity in the peripheral auditory system would be detrimental to subsequent neural processing because it would eliminate information that could otherwise be recovered by temporal averaging (integration) or filtering, which can in principle pull an arbitrarily small periodic signal out of aperiodic background noise. This ability is crucial for systems designed to detect small noisy signals. For example, a sinusoidal signal that is superimposed on additive white noise can be passed through a narrow-band linear filter that leaves the signal unchanged while reducing the noise in proportion to the bandwidth of the filter. Narrowing the filter's bandwidth can thus increase the signal-to-noise ratio as much needed to detect an arbitrarily small periodic signal, albeit at the expense of temporal resolution (Bracewell, R. N., 1999). The auditory system's use of temporal integration to improve signal-to-noise ratio is seen experimentally as an inverse relation between threshold and sound duration (Jeffress, L. A., 1968; Heil, P. and Neubauer, H., 2001; 2003). The observation that sounds too soft to be audible can nevertheless influence the audibility of subsequent sounds (Plack, C. J. *et al*., 2006) supports the idea that subthreshold sounds still produce some response.

The peripheral auditory system eliminates any threshold cut-off in the afferent response to faint sounds by eliminating all slack from the system, ensuring that arbitrarily weak sounds evoke a change in ANF firing rate that is proportional to the sound amplitude, at least for low-frequency tones. This begins with mechanosensory transduction, which uses feedback to maintain partial activation of the transduction channels even in complete silence. The resulting resting transduction current places the hair cell's resting membrane potential in a range where the presynaptic calcium channels are also partially activated (Koschak, A. *et al*., 2001; Xu, W. and Lipscombe, D., 2001; Johnson, S. L. *et al*., 2005). This steady-state activation of the calcium current (i.e., the random, thermally driven, independent gating of individual calcium channels that occurs at constant membrane potential) may be sufficient to catalyze baseline transmitter release (Brandt, A. *et al*., 2005) that drives the so-called spontaneous spiking in ANFs (Liberman, M. C. and Kiang, N. Y. S., 1978; Sewell, W. F., 1984; Glowatzki, E. and Fuchs, P. A., 2002; Keen, E. C. and Hudspeth, A. J., 2006). Thus, each stage of processing is maintained in a partially active state even in complete silence, thereby avoiding a threshold nonlinearity and the resulting loss of

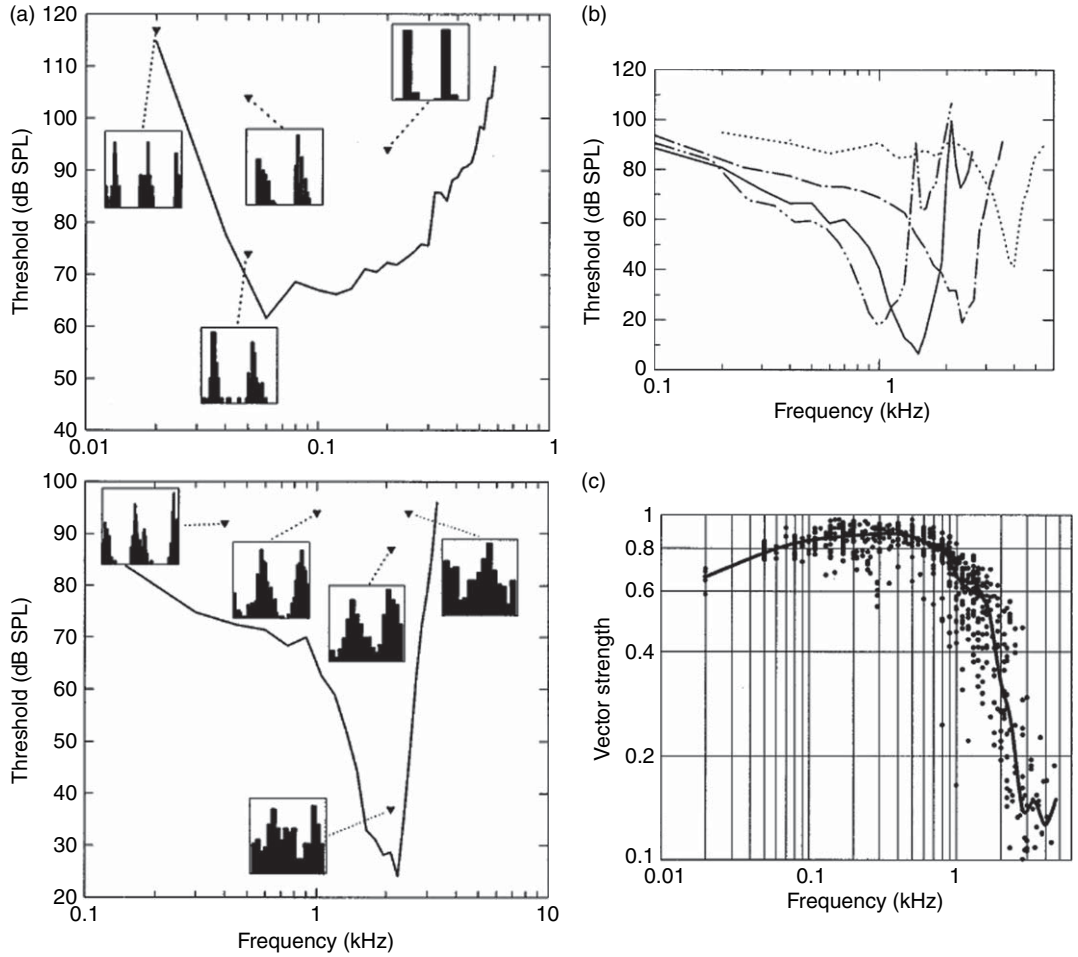

Figure 2 Tuning curves and phase locking in avian (emu) auditory nerve fibers (ANFs). (a) The sound pressure level (SPL) required to evoke a criterion response, in this case, a 20 Hz increase in ANF firing rate above the spontaneous rate (SR), plotted as a function of the frequency of the tonal stimulus. This type of measurement is often called the fiber's threshold, although it does not mean that the fiber fails to respond to less intense sounds, only that the response falls below the experimenter's criterion. Data from two ANFs are shown. Each panel shows one fiber's tuning curve as a continuous line and phase histograms (insets) from the same fiber, each spanning a time frame of two cycles on the *x*-axis and displaying the probability of a spike in particular time bins within the cycle. The stimulus for the insets was at the frequency-level combinations indicated by the associated filled, inverted triangles. The phase relationship of spike occurrence to the period of the tonal stimulus changes as a function of frequency, but at the characteristic frequency (the low point on the curve) the phase relationship does not vary with changes in sound intensity (dB SPL). (b) Tuning curves for four ANFs of different characteristic frequency. (c) When vector strength (a measure of the degree of phase locking, on a scale of 0 to 1, derived from phase histograms like those shown in (a)) is plotted as a function of stimulus frequency around characteristic frequency for 73 different afferent fibers, it is apparent that cochlear ANFs in the emu exhibit a sharp decline in phase-locked firing at frequencies above 1 kHz. Reprinted with permission from Manley, G. A., Köppl, C., and Yates, G. K., J. Acoust. Soc. Am., Vol. 101, pages 1560-1573, 1997. Copyright 1997, American Institute of Physics.

information about small signals. Because several steps in auditory reception involve discrete all-or-none events (e.g., the opening of individual ion channels, the fusion of individual synaptic vesicles (SVs) with the plasmalemma, and the generation of individual action potentials in ANFs), the presence of thermally driven noise in the system is crucial to maintaining high sensitivity to small sounds (Indresano, A. A. *et al.*, 2004). This phenomenon has been studied in many physical systems under the odd name of stochastic resonance.

At frequencies above a few kilohertz, where sound perception relies on nonlinear transduction at the foot of the stimulus–response curve to produce the

DC component of the receptor potential (see Section 3.22.6), a nonlinear response to small sounds may be unavoidable.

Fibers that are the most sensitive to sound also have the highest SR. The equivalent statement in terms of threshold is that SR varies inversely with threshold. In cats, ANFs have been divided into three classes based on SR: low-SR fibers (<0.5 Hz) have the highest threshold (20–60 dB higher than high-SR fibers), high-SR fibers (≥18 Hz) have the lowest thresholds, and medium-SR fibers have an intermediate sensitivity (Merchan-Perez, A. and Liberman, M. C., 1996). Because ANFs with the same CF can have high-, intermediate-, or low-SR, it seems likely that a single IHC forms synapses with representatives of all three functional groups.

Unlike many types of neurons that fire either with a fairly constant interspike interval or in bursts, the exponential distribution of interspike intervals for baseline activity in mammalian ANFs suggests that their activity in the absence of sound is driven by independent random events (i.e., it is a Poisson process), except during a neural refractory period following each spike (Johnson, D. H. and Kiang, N. Y. S., 1976) rather than by an oscillation in the pre- or postsynaptic membrane potential or by any of the other well-known mechanisms that underlie bursting or rhythmic firing in neurons. The independent events may be the brief openings of individual presynaptic calcium channels, in which case the afferent synapses onto ANFs with higher SRs could have more calcium channels or a higher probability of transmitter release in response to the opening of a single calcium channel. Another possibility to explain the correlation between an ANF's sensitivity and its SR is that the voltage dependence of the calcium channels at high-SR synapses is shifted such that the channel's resting open probability is increased, which would also move the resting potential to a steeper place on the channel's sigmoidal activation curve. In all of these cases, high SR would be associated with greater sensitivity to sound. Since a single hair cell can make synapses onto several ANFs that have widely varying SRs, these differences must be specific to individual synapses.

If the Poisson events that trigger exocytosis are the openings of individual calcium channels, then a simple calculation shows that the probability of exocytosis associated with each channel opening is likely to be very small. Calcium channels in hair cells have mean open times of <1 ms and a steady-state open probability of ∼10% at the resting potential, implying a mean closed time of <10 ms. If calcium channels in IHCs have properties similar to these, then each channel is expected to generate >100 openings per second at the resting potential, and the ensemble of ∼100 calcium channels at a typical AZ are expected to generate $>10^4$ openings per second. Given that the highest SRs in ANFs are $\sim 100\,s^{-1}$, fewer than 1% of calcium channel openings are predicted to trigger exocytosis.

3.22.2.3 Innervation Patterns and the Function of Auditory Organs

The pattern of afferent innervation onto hair cells contributes greatly to the response properties observed in afferent fiber recordings. To illustrate this, we will consider two very different auditory organs of the inner ear: the mammalian cochlea and the frog sacculus.

As mentioned above, sensory information from a single IHC in the mammalian cochlea diverges onto multiple ANFs, which can be regarded as a set of parallel channels that relay information from a single IHC to the brain. Because each IHC has a slightly different CF, and a slightly different phase relationship to the sound, restricting each ANF's input to a single IHC preserves these two important features of the cochlear tonotopy. Having multiple outputs from each IHC with different sensitivities (range fractionation) may be important for maintaining a high signal-to-noise ratio for faint sounds in some ANFs while avoiding saturation by loud sounds in other ANFs. Even if some of the ANFs have identical response properties, maintaining redundant information channels can be important for increasing the signal-to-noise ratio. Two important sources of noise are uncertainty in when (or whether) a spike will be generated in a given ANF and variation in the conduction time of ANF spikes to the brain. This noise can, in principle, be reduced by combining information transmitted over separate channels that have independent noise sources. Each ANF postsynaptic to a given IHC shares a common input signal (the hair cell's membrane potential), but the subsequent steps of synaptic transmission, spike generation and conduction to the brain are carried out independently in each AFN, and therefore are subject to independent noise. The innervation pattern of the mammalian cochlea thus appears to be optimized to provide the spectral and temporal information needed for complex computations involved in speech recognition and generating a map of auditory space.

The frog sacculus has a very different structure and pattern of innervation (reviewed in Smotherman, M. S. and Narins, P. M., 2000). It is (in addition to its function as a vestibular organ) exquisitely sensitive to both airborne sound and substrateborne vibration (Koyama, H. *et al.*, 1982). The frog saccular hair cells reside in a roughly circular patch of sensory epithelium beneath the otolithic membrane, and all are attached to it through their kinocilia. There is no evidence of tonotopic organization. Instead, the hair cells fall into only a few anatomical classes, suggesting that many may be functionally equivalent to each other (Edmonds, B. *et al.*, 2000). Unlike the mammalian cochlea, each saccular afferent neuron branches to contact many hair cells (Lewis, E. R. *et al.*, 1982). Summation of synaptic inputs from multiple hair cells is expected to increase the sensitivity and, perhaps more important, the signal-to-noise ratio of ANFs from the frog sacculus, which is expected to contribute to the organ's extreme sensitivity to sound and vibration.

3.22.3 Hair Cells

Hair cells are part of the tight epithelium that separates endolymph from perilymph. Each hair cell is sealed to its neighbors by tight junctions that form an extracellular diffusion barrier across the epithelium and divides the cell membrane into an apical domain that is primarily involved in mechanosensory transduction and a basolateral domain where the synapses reside (Figure 1(b)). Hair cells are both pre- and postsynaptic, and have other neuronal properties, including voltage- and calcium-gated ion channels that, in concert with the transduction current and the membrane's electrical capacitance, determine how the membrane potential changes with time. The hair cell's compact shape has important consequences for both the electrical signal and the ensuing calcium signal that controls transmitter release at afferent synapses.

3.22.3.1 Hair Cell Shape in Relation to Synaptic Signaling

The hair cell body has a diameter-to-length ratio that is too large to allow significant spatial variation in the membrane potential, except in OHCs of the mammalian cochlea, where extensive internal membranes lining the plasmalemma might impede intracellular current flow (Nakagawa, T. *et al.*, 2006). Other types of hair cells, including IHCs of the mammalian cochlea, are expected to be nearly isopotential even to the tips of the stereocilia (Roberts, W. M. *et al.*, 1990). This means that the electrical signal for synaptic transmission is the same at each of the afferent synaptic sites, and implies that the different properties of the afferent synapses on a single hair cell must arise downstream of the electrical signal. Similarly, the membrane capacitance is expected to attenuate high-frequency voltage oscillations to the same degree at all AZs in a given hair cell, leaving only a steady depolarization in response to high-frequency sounds (Section 3.22.6).

The hair cell's large radius of membrane curvature compared to the diameter of a single synaptic AZ (several micrometers vs. hundreds of nanometers) simplifies the understanding and modeling of afferent synaptic transmission because for some purposes the membrane can be regarded as a planar boundary separating two infinite spaces (Neher, E. and Augustine, G. J., 1992; Roberts, W. M., 1994). Clearly, the hair cell's ~1 pl volume is less than infinite and cannot serve as an infinite sink for calcium entering at synapses, but as long as calcium extrusion can keep pace with calcium entry, the details of how and where calcium is pumped back into the extracellular space are expected to be less important than in the confined space of a typical presynaptic bouton.

3.22.3.2 The Synaptic Body and Synaptic Vesicle Pools

Afferent synapses on all hair cells and related electroreceptors are distinguished by a prominent presynaptic structure, the synaptic body (SB). One or more SBs are found at each site of synaptic contact, in close association with the presynaptic plasma membrane (Figures 3 and 4). Numerous functions have been proposed for the SB (Sjostrand, F. S., 1958; Bunt, A. H., 1971; Gray, E. G. and Pease, H. L., 1971; Osborne, M. P. and Thornhill, R. A., 1972; Wagner, H.-J., 1978; King, T. S. and Dougherty, W. J., 1982; Schmitz, F. *et al.*, 2000; Lenzi, D. and von Gersdorff, H., 2001; Parsons, T. D. and Sterling, P., 2003), but none proved.

The hair cell contains a large population of ~40 nm, clear-core vesicles that are presumed to contain the neurotransmitter, glutamate. These SVs have been partitioned into several conceptual pools, defined either structurally with EM or functionally

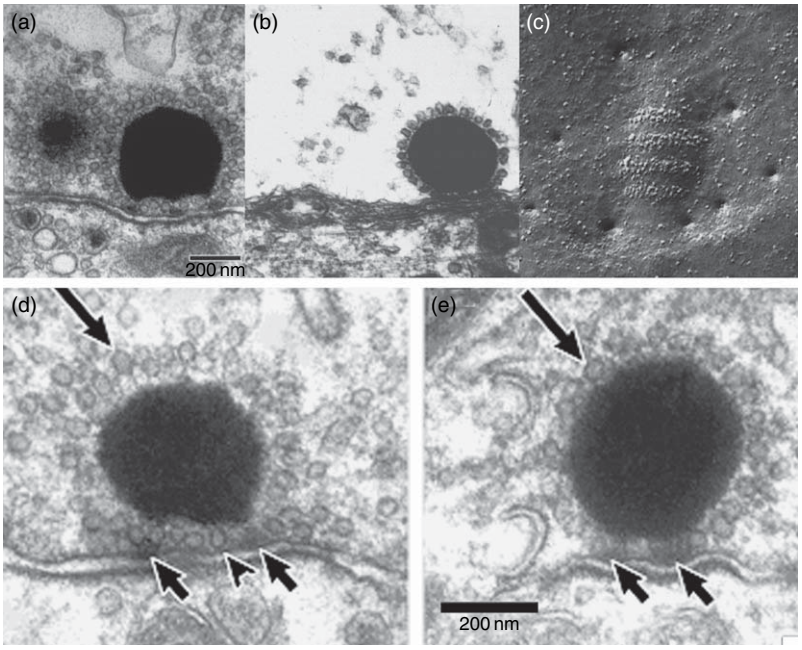

Figure 3 Afferent synapse ultrastructure. All panels are electron micrographs of afferent synapses in frog saccular hair cells. (a) Each site of synaptic contact between a hair cell (top) and afferent nerve ending (bottom) typically contains one synaptic body, which is darkly stained and surrounded by ~40 nm-diameter vesicles. A second synaptic body (SB) is faintly visible to the left. The region of close apposition between pre- and postsynaptic membranes is marked by a fuzzy appearance that extends 100–400 nm beyond the edge of the synaptic body, but the presumed region where synaptic vesicles release their contents (the active zone) is restricted to the area beneath the SB and perhaps ~100 nm beyond. The presynaptic membrane at the active zone contains several densities that anchor the SB. (b) The SB and its attached vesicles remain anchored to the presynaptic active zone after the cell is broken open in extracellular saline (contains 1.8 mM calcium) and the cytoplasm washed away prior to fixation. (c) A freeze-fracture electron micrograph shows rows of particles in the presynaptic membrane that may align with the presynaptic densities and correspond to ion channels. The membrane dimples around the periphery of the active zone are most likely the openings of membrane tubules rather than sites of vesicle fusion, which are expected to occur closer to the ion channels at the active zone. (d, e) Filamentous links tether the SB to the cytomatrix at the active zone (short arrows) and synaptic vesicles to the SB (long arrows). Synapses that had been inhibited before and during fixation (d) had a high density of docked vesicles in the space between the SB and the plasmalemma (arrowhead points to one). Synapses that had been stimulated before and during fixation (e) had few docked vesicles and numerous cisternal structures in the cytoplasm. (c) Reproduced with permission from Roberts W. M. 1994. with electrophysiological assays of SV fusion and neurotransmitter release.

Experiments on a wide variety of chemical synapses in many animals have shown that SVs can generally be assigned to one of three groupings: the readily releasable pool (RRP), the recycling pool, and the reserve pool (reviewed in Rizzoli, S. O. and Betz, W. J., 2005). Parallel definitions of these pools at hair cell afferent synapses are useful to facilitate comparisons with more conventional chemical synapses, although this is hampered somewhat by their different anatomical and functional characteristics. At both types, maximal activation of the presynaptic calcium current exhausts a small SV pool, defined as the RRP, within a few milliseconds. At conventional synapses, the RRP comprises 1–2% of the total vesicle population, but considering the hair cell cytoplasm as an unrestricted volume for SV movement containing hundreds of thousands of SVs (Lenzi, D. *et al.*, 1999; Holt, M. *et al.*, 2004), the RRP in hair cells comprises a miniscule fraction of the total (Moser, T. and Beutner, D., 2000; Schnee M. E. *et al.*, 2005; Rutherford, M. A. and Roberts, W. M., 2006).

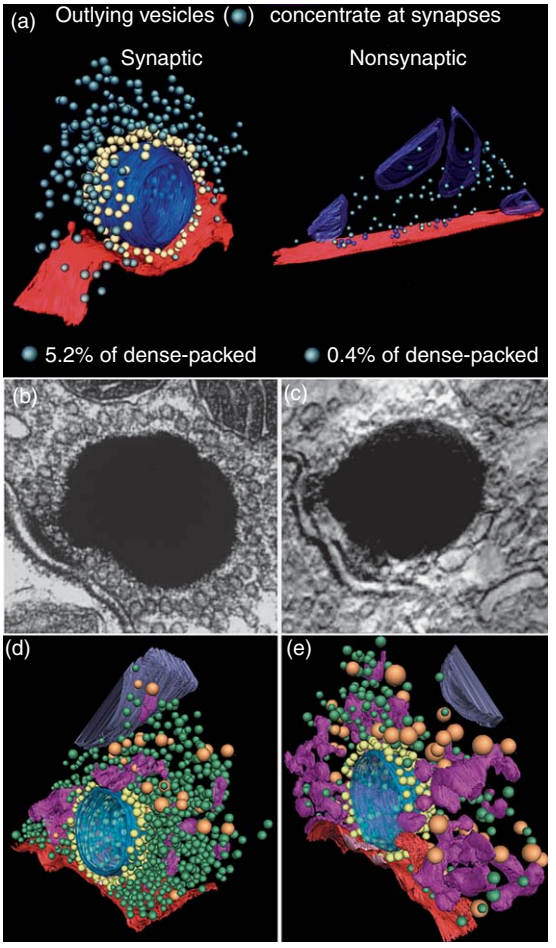

Figure 4 Tomographic reconstructions of afferent synapses in frog saccular hair cells. (a) Tethered vesicles (yellow) surround the SB (blue), which lies close to the plasmalemma (red) at the Active zone (AZ). Other (outlying) synaptic vesicles (green) are also highly concentrated within a few hundred nanometers of the SB, and populate the rest of the cytoplasm at much lower density. (b) An inhibited synapse shows mostly spherical vesicles around the SB. (c) A stimulated synapses has numerous irregular membrane structures near the SB that could be the result of compound vesicle fusion and/or membrane retrieval. (d, e) Tomographic reconstructions give a clear view of the more extensive cisternal structures (magenta) at stimulated synapses (e) compared to inhibited synapses (d). Coated vesicles (orange) and mitochondria (dark blue) are also shown. Other colors are the same as in (a). (a) Reproduced with permission from Lenzi, D., Runyeon, J. W., Crum, J., Ellisman, M. H., and Roberts, W. M. 1999. Synaptic vesicle populations in saccular hair cells reconstructed by electron tomography J. Neurosci. 19, 119–132; Copyright by the Society for Neuroscience. (d,e) Reprinted from Lenzi, D., Crum, J., Ellisman, M. H., and Roberts, W. M. 2002 Depolarization redistributes synaptic membrane and creates a gradient of vesicles on the synaptic body at a ribbon synapse. Neuron 36, 649–659; Copyright (2002) with permission from Elsevier.

At conventional synapses, the RRP is generally thought to correspond to the docked vesicles, those seen in EM to be in contact with the plasmalemma at the AZ. The corresponding pool of morphologically docked vesicles at ribbon synapses consists mostly of vesicles that occupy the space between the SB and the plasmalemma at each AZ (Figures 3 and 4). Differences in the precise criteria used for anatomical classification of vesicles can cause estimates of the size of the docked vesicle pool to differ by a factor of two, even in careful quantitative studies.

There is ambiguity about how to classify vesicles that are tethered to the SB but do not contact the plasma membrane. Direct evidence that these vesicles even participate in transmitter release under normal conditions is scant (Siegel, J. H. and Brownell, W. E., 1986), but assuming that they do, are they part of the RRP, the recycling pool, or some other pool? One reason to think that even though they reside far from the plasmalemma they might still be in the RRP is that they may be able to fuse with each other, forming a chain that connects to the cell surface (reviewed in Parsons, T. D. and Sterling, P., 2003; Edmonds, B. W. *et al.*, 2004). Figure 4(c) shows what may be a chain of fused vesicles. If the morphological criterion that has been used to determine whether a vesicle is docked to the plasmalemma is applied to vesicles on the SB, then many of these vesicles are morphologically docked to each other, and thus could conceivably be ready to fuse together, although the calcium signal is expected to be highly attenuated more than a few vesicle diameters from the calcium channels on the cell surface (Roberts, W. M., 1994). Alternatively, the type of structures shown in Figure 4(c), which were observed after extended depolarization in high potassium (Lenzi, D. *et al.*, 2002), could reflect membrane retrieval.

The available physiological evidence indicates that the RRP in the frog sacculus and mouse cochlea is much smaller than the total pool of SB-associated vesicles, and is close to the number of vesicles docked at the plasmalemma (Khimich, D. *et al.*, 2005; Rutherford, M. A. and Roberts, W. M., 2006), which supports the more conventional hypothesis that only vesicles docked at the plasmalemma are part of the RRP, and that other SB-associated vesicles are part of the recycling vesicle pool that replenishes the RRP. Physiological correlates of these anatomical definitions are discussed in more detail in the following sections of this chapter.

Tens of thousands of clear-core vesicles are found in the hair cell cytoplasm within several hundred

nanometers of the cell surface, and hundreds of thousands more reside in the vast cell interior. They occur at a low average density in frog saccular hair cells (0.4% of dense packed = ~100 vesicles per μm^3), but are much more concentrated within 700 nm of each synapse (5–10% of dense packed = ~1200–2400 vesicles per μm^3; Lenzi, D. *et al.*, 1999; 2002). The contribution of these vesicles to synaptic transmission under normal physiological conditions is unclear. At conventional synapses, there is a physiologically distinct (but sometimes not anatomically distinct; Rizzoli, S. O. and Betz, W. J., 2005) recycling pool of SVs that are reused preferentially by local endocytosis (Pyle, J. L. *et al.*, 2000; Stevens, C. F. and Williams, J. H., 2000), whereas vesicles in the reserve pool enter the exocytic pathway only under strong stimulus conditions that also cause bulk endocytosis and vesicle reconstitution through an endosomal compartment. It remains unknown whether hair cell afferent synapses have distinct recycling and reserve SV pools.

The AZ at most brain synapses contains only a few docked vesicles, and a single presynaptic action potential seldom evokes exocytosis of neurotransmitter from more than one of them, with frequent failures (Dobrunz, L. E. and Stevens, C. F., 1997; for a review see Sudhof, T. C., 2000). In contrast, the docked vesicle pool is considerably larger at AZs in hair cells of the turtle papilla (mean of 30; Schnee, M. E. *et al.*, 2005), mouse cochlea (16–30, IHC; Khimich, D. *et al.*, 2005), and the frog sacculus (mean of 43; Lenzi, D. *et al.*, 2002). Furthermore, both pre- and postsynaptic assays of SV exocytosis (see Sections 3.22.5–3.22.7) have indicated that more than one SV can fuse in response to a single, brief presynaptic stimulus (reviewed in Fuchs, P. A., 2005). The stimulus to open voltage-gated calcium channels (VGCCs) in hair cells is not an all-or-none action potential that lasts on the order of 1 ms, rather, they respond to depolarizations of varying duration and intensity with graded release of neurotransmitter. Thus, while some generalizations can be made across all synapse types, there may be important differences between SV pools at conventional synapses and hair cell afferent synapses.

3.22.3.3 Calcium Buffering in Hair Cells

Exogenous calcium buffer can be introduced into a hair cell through a micropipette recording electrode, and has been shown to influence synaptic transmission. Interestingly, a high concentration of calcium buffer with fast binding kinetics is required to interfere with exocytosis from the RRP, whereas refilling of the RRP can be inhibited by low concentrations of slower buffer (Moser, T. and Beutner, D., 2000). It is concluded that although both processes are regulated by calcium, refilling of the RRP involves signaling over a longer distance, and is therefore more susceptible to disruption by calcium buffers. To understand the interaction between calcium ions and calcium buffers that can diffuse in cytoplasm one must think about the rates of binding and diffusion, not just equilibrium binding of calcium to the buffer. A brief introduction to the essential concepts needed to understand the nonequilibrium interaction between a mobile calcium buffer and the calcium ions that enter through a calcium channel and diffuse into a large cytoplasmic volume is given below.

High concentrations of calcium-binding proteins can limit the spread of calcium signals within a cell (Roberts, W. M., 1994). This may be particularly important in hair cells, because they use calcium signals for several distinct cellular processes, including feedback inhibition of the transduction current, which involves calcium entry and action at the stereociliary tips (see Chapter Hair Cell Transduction and Adaptation: Physiology and Molecular Mechanisms), and efferent synaptic transmission see Chapter Efferent System at postsynaptic sites, which intermingle with afferent presynaptic sites on the hair cell's basolateral surface. In addition to localized transmembrane calcium signals, hair cells also exhibit localized calcium-induced calcium release from intracellular stores near sites of efferent contact (Lioudyno, M. *et al.*, 2004).

The equilibrium interaction between calcium and a molecule that has a single calcium-binding site is characterized by a single number, the dissociation constant, K_D (units: molar, M), or its reciprocal, K_A (M^{-1}):

$$K_D = \frac{[Ca][B]}{[CaB]}$$

where [Ca] and [B] are the concentrations (M) of free Ca and free buffer, and [CaB] is the concentration of calcium bound to the buffer. Free means that they are able to interact with each other (i.e., not already bound to something else, hidden inside an organelle, etc.); whether or not they are free to diffuse in the cytoplasm is a separate issue that is also important. Time does not appear in the units of these variables. It is assumed that enough time has elapsed for equilibrium to be attained.

The equilibrium equation does not apply near an open calcium channel because equilibrium is never

reached while the calcium current persists (which requires an extrusion mechanism to keep the cell from filling up with calcium). The existence of a calcium current is *prima facie* evidence of disequilibrium, at least locally around the mouth of the channel. We will not specifically consider the calcium pump here, except to note that the maximum flux of calcium ions through a single pump ($\sim 10^3\,s^{-1}$) is roughly one ten thousandth the flux through an open calcium channel ($\sim 10^7\,s^{-1}$), so that the local calcium gradient around a single pump is miniscule compared to the gradient near the mouth of a single calcium channel. Therefore, it makes sense to consider the calcium extrusion process to be distributed over a large region of cell surface, and ignore its effect on the localized region of extremely high free calcium near an open calcium channel.

Two parameters, k_{on} ($M^{-1}\,s^{-1}$) and k_{off} (s^{-1}), are needed to describe the kinetics of calcium binding to a single-site buffer. $k_{on}[B]$ and k_{off} are, respectively, the rate constants for calcium binding to and unbinding from the buffer. The three parameters, k_{on}, k_{off}, and K_D are related by $K_D = (k_{off}/k_{on})$, so any two specify the third.

A calcium ion is initially free as it enters the cell through a calcium channel. The mean time required to encounter and bind to a buffer molecule is $1/(k_{on}[B])$, which for the buffering conditions encountered in many hair cells ($[B] >> K_D$) is close to the equilibration time constant (τ) in response to a step change in free calcium:

$$\tau = \frac{1}{k_{on}([B] + K_D)}$$

During this time, a free calcium ion diffuses a characteristic distance of

$$\lambda = \sqrt{\tau D_{Ca}}$$

where D_{Ca} is the diffusion coefficient for free calcium in cytoplasm (Neher, E. and Augustine, J. G, 1992; Roberts, W. M., 1993). The parameters τ and λ are, respectively, the time and space constants for calcium binding to the buffer in the vicinity of an open calcium channel.

If the distance between the presynaptic calcium channels and the calcium sensors that trigger exocytosis is substantially less than λ then the buffer has little effect. If the distance is substantially greater than λ then the buffer has time to come into equilibrium with global free calcium and binding kinetics are not important. If the distance is similar to λ then the binding kinetics are important and the buffer's effects can be complex. The diffusion coefficient for the buffer in cytoplasm is also important because slow diffusion reduces the rate at which calcium-free buffer is replenished near the open channel, which reduces the local [B], and in turn locally increases both τ and λ. At hair cell afferent synapses, exocytosis of RRP vesicles falls into the first category, where cytoplasmic buffers are irrelevant, but some other important calcium-dependent steps in the SV cycle appear to fall into the complex category, where buffer concentration, binding kinetics, and diffusion coefficient all come into play.

To assign approximate values to τ and λ one needs to know the concentration and k_{on} for the predominant diffusionally mobile calcium buffer(s) in the cell. Many types of hair cells are intensely labeled by fluorescent antibodies against one or more of the diffusible calcium-binding proteins calbindin-D28k, calretinin, parvalbumin-α, and parvalbumin-β (also known as oncomodulin or PV-3). For example, some hair cells in the frog sacculus contain calretinin at a concentration above 1 mM, which provides more than 5 mM calcium-binding sites (Edmonds, B. *et al.*, 2000). Other frog saccular hair cells contain predominantly parvalbumin β, at the extraordinary concentration of 4 mM (Heller, S. *et al.*, 2002), which amounts to 8 mM calcium-binding sites. OHCs in the mammalian cochlea contain different calcium-binding proteins than are found in the IHCs, and appear to express them at a tenfold higher concentration (calbindin-D28k and parvalbumin-β equivalent to 5 mM calcium-binding sites; Hackney, C. M. *et al.*, 2005). These extreme concentrations of calcium buffer are certain to have important consequences for many calcium signals in the cell. It is also worth remembering that some calcium-binding proteins may serve both as buffers and as calcium sensors that influence exocytosis or participate in other steps in the SV cycle.

For typical values of $K_D = 1\,\mu M$ and $k_{on} = 10^7\,M^{-1}\,s^{-1}$, the buffer space constant and time constant in a cell that has a moderate calcium buffer concentration of $[B] = 100\,\mu M$ are $\lambda = 450\,nm$ and $\tau = 1\,ms$. Increasing the buffer concentration 100-fold to 10 mM decreases λ to 44 nm and τ to 10 µs. From this calculation, one can see that an extremely high concentration of a calcium buffer can reduce the buffering space constant from approximately the diameter of the entire AZ (Figure 3(c)) to approximately the diameter of a single SV, thereby minimizing the overlap of calcium

domains around each open calcium channel, particularly at barely perceptible sound intensities where only a few calcium channels are open at each afferent synapse. The close association between calcium channels and AZs (Lewis, R. S. and Hudspeth, A. J., 1983; Art, J. J. and Fettiplace, R., 1987; Roberts, W. M. *et al.*, 1990; Issa, N. P. and Hudspeth, A. J., 1994; Martinez-Dunst, C. *et al.*, 1997; Rodriguez-Contreras, A. and Yamoah, E. N., 2001; Zenisek, D. *et al.*, 2003; Brandt, A. *et al.*, 2005) means that steep spatial calcium gradients and the nonequilibrium calcium binding to buffer are important at afferent synapses.

At distances on the order of λ from an open channel, the buffer serves as a calcium sink, and can greatly reduce the free calcium concentration (Roberts, W. M., 1994). At larger distances, where free calcium falls below the buffer's K_D, the buffer becomes a calcium source as it dumps its bound calcium, although the large volume available to receive this calcium means that the calcium rise associated with unbinding from the buffer is orders of magnitude smaller than the calcium concentration near the source. Because the buffer molecules are large compared to a calcium ion, bound calcium diffuses more slowly than free calcium. The net result is that the buffer can greatly increase total calcium near an open calcium channel, and can slightly increase free calcium at certain distances from the channel, but its main effect is to greatly reduce the extremely high concentration of free calcium that accumulates near the channel (i.e., at distances on the order of λ).

More detailed discussions of these and other properties of mobile calcium buffers are in the literature (e.g., Stern, M. D., 1992; Roberts, W. M., 1993; 1994; Dargan, S. L. and Parker, I., 2003). One interesting result is that the average distance that a calcium ion travels while remaining bound to the buffer is >1 μm, which is large compared to the AZ diameter. Thus, the mobile buffer gives a calcium ion only one brief chance to exert its effect. Either it binds to its target, such as the calcium sensor that triggers exocytosis, or it is captured by the mobile buffer and is carried away. If the buffer has reasonably fast binding kinetics ($k_{on} = 10^7\,M^{-1}\,s^{-1}$) and provides 5–10 mM of mobile binding sites for Ca (Edmonds, B. *et al.*, 2000; Heller, S. *et al.*, 2002), then the average time available for a calcium ion to encounter and bind to its target (i.e., the binding time constant, τ) is only 10–20 μs.

3.22.4 Ribbon Synapses – A Small but Diverse Class

The SBs of hair cells are homologous to the presynaptic ribbons found in rods, cones, and bipolar cells in the retina, and pinealocytes in the pineal body. Like hair cells, these cells usually do not make action potentials. Because of their anatomical, physiological, and molecular similarities, we include the afferent synapses of hair cells in the class of ribbon synapses, but one should also keep in mind the differences, including, for example, the slow-time scale of the visual system compared to the auditory system.

Ribbon synapses are understood to be specialized for sustained transmitter release. For example, vertebrate photoreceptors release neurotransmitter continuously in the dark (Rea, R. *et al.*, 2004) and the hair cell afferent synapse is active in the absence of an applied stimulus (Siegel, J. H., 1992). However, the hair cell is also capable of releasing transmitter phasically (e.g., EPSPs that are correlated with the periodicity of the stimulus for afferent fibers at frequencies up to a few kilohertz; Figures 1(c) and 2(c), see also Section 3.22.6). The details of synaptic physiology that vary among ribbon synapses from different tissues and cell types are likely to be essential for their function (for a review, see Sterling, P. and Matthews, G., 2005). Nevertheless, the first synapse in the pathways for vision, hearing, balance, and lateral line senses in all vertebrate animals is a ribbon synapse.

3.22.4.1 The Synaptic Body (Ribbon) and Its Vesicles

The term ribbon originates from the flat, almost 2D morphology of the presynaptic structures observed in transmission EMs of retinal photoreceptors and bipolar cells. Serial reconstructions of gluteraldehyde-fixed hair cells from many preparations, including mammalian cochlea, have shown that the SB in hair cells has a more spherical or ellipsoid shape. IHCs rely exclusively on ribbon synapses for afferent transmission. The role of SBs in OHCs is more uncertain as they (the SBs) are far fewer and often seen only during development (Smith, C. A. and Sjostrand, F. S., 1961; Siegel J. H. and Brownell W. E., 1981; Sobkowicz, H. M. *et al.*, 1986).

Although SBs are heavily stained by osmium, which typically labels lipid membranes, they are thought to be composed primarily of protein

(Krstic, R., 1976). The osmiophilic nature of the SB is well-known because OsO_4 is a common EM fixative and is electron-dense. Perhaps more relevant to function, the ribbon has been reported to bind both calcium and phosphate (Schmitz, F. and Drenckhahn, D., 1991), although there is no evidence that it binds or releases these ions in the process of synaptic transmission.

SBs at AZs are always found in association with ~40 nm-diameter clear-cored vesicles, which are attached to it by thin filaments (Usukura, J. and Yamada, E., 1987) and often cover its surface nearly completely (Figures 3 and 4; Lenzi, D. *et al.*, 2002). SBs can sometimes be found in the cell interior, either singly or in clusters, where they are also covered in vesicles (Miller, M. R. and Beck, J., 1987). The molecular identity of the filaments is not known, except that they are thought not to contain synapsins I or II, which form filaments linking SVs to cytoskeleton at other synapses (Hirokawa, N. *et al.*, 1989), but are absent from ribbon synapses (von Kriegstein, K. *et al.*, 1999). Based on antibody labeling, the filaments could contain the KIF3A subunit of the kinesin 2 motor complex (Muresan, V. *et al.*, 1999), which forms 50 nm-long rods *in vitro* (Yamazaki, H. *et al.*, 1995), or possibly one or more of the many other KIF3 isoforms that may cross react with the antibody.

SBs and ribbons can be regarded as elaborations of the cytomatrix at the active zone (CAZ) seen at all synapses (Zhai, R. G. and Bellen, H. J., 2004), but in EM the SB appears as a separate structure, connected to the CAZ by filamentous links (Usukura, J. and Yamada, E., 1987; Lenzi, D. *et al.*, 2002). The tight association between the SVs and the SB, and between the SB and the presynaptic plasma membrane is evident in cells that were broken open prior to fixation (Figure 3(b)). If the binding were weak or disrupted by exposure to the high-calcium concentration of extracellular saline, these structures would not have remained behind while the rest of the cytoplasm was washed away.

3.22.4.2 Molecular Specializations of Ribbon Synapses

Understanding of the molecular composition of hair cell afferent synapses has begun (Figure 5), but is far from complete (Wagner, H.-J., 1997). A protein, Ribeye

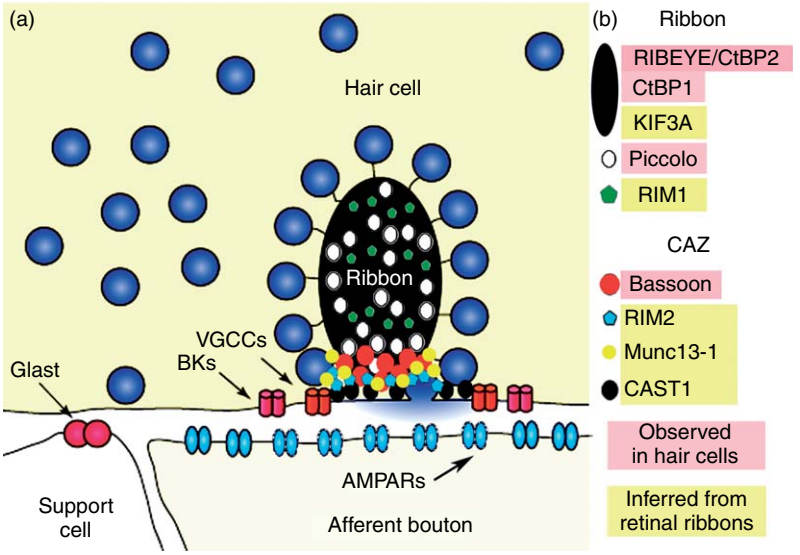

Figure 5 Molecular specializations of the hair cell ribbon synapse. (a) Localization of proteins associated with the synaptic ribbon and plasma membrane density of the cytomatrix at the active zone (CAZ), labeled in (b). Voltage-gated calcium channels (VGCCs) are clustered underneath the ribbon and juxtaposed to postsynaptic α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA)-type glutamate receptors. In some hair cells, presynaptic calcium-sensitive voltage-gated (BK) potassium channels intermingle with the VGCCs. Glutamate transporters in supporting cells clear neurotransmitter from the cleft. Bassoon anchors the ribbon to the Cytomatrix at the active zone (CAZ) plasma membrane density via its interaction with the RIBEYE. Bassoon, RIBEYE/CtBP2, CtBP1, and Piccolo have been observed at hair cell afferent synapses. The existence of the other proteins at the hair cell's ribbon synapse is by inference from observations at retinal ribbon synapses (tom Dieck, S. *et al.*, 2005). Reproduced from The Journal of Cell Biology, 2005, 168, 825–836 by Copyright permission of The Rockefeller University Press; and Reprinted from Curr. Opin. Neurobiol. Vol. 13, Fuchs, P. A., Glowatzki, E., and Moser, T., The afferent synapse and cochlear hair cells, 452–458, Copyright 2003, with permission from Elsevier.

(Schmitz, F. *et al.*, 2000), has been identified that appears to be a component of all synaptic ribbons, and is expressed nowhere else. This finding justifies exclusion of T-bar synapses of arthropods (e.g., *Drosophila*) from the class of ribbon synapses because the *Drosophila* genome contains no DNA sequences that code for a homolog of the unique exon 1 of the Ribeye protein (Bradford, Y. and Roberts, W. M., unpublished observations). Ribeye is one of two known protein products of the CtBP2 gene. The other product, CtBP2, is a transcription regulator (reviewed in Chinnadurai, G., 2002). A recent report suggests that the CtBP1 protein, which is the product of a closely related gene and also a known transcription regulator, is a presynaptic component of both hair cell (Moser, T., personal communication) and retinal (tom Dieck, S. *et al.*, 2005) ribbon synapses, as well as conventional synapses, raising the possibility that the ancestral CtBP protein had a presynaptic function in addition to being a transcriptional corepressor, and conceivably could link synaptic activity to gene expression. The CAZ-associated protein Bassoon was recently shown to anchor the ribbon at the photoreceptor synapse via a physical interaction with Ribeye (tom Dieck, S. *et al.*, 2005). Bassoon and the related protein Piccolo, are also present at hair cell afferent synapses (Khimich, D. *et al.*, 2005). Bassoon appears to interact with both Ribeye and CtBP1, which are both localized to ribbons even in the absence of functional Bassoon protein.

Drosophila has a single CtBP gene that produces a transcription regulator essential for embryonic development (Nibu, Y. *et al.*, 1998; Poortinga, G. *et al.*, 1998), but it is not known whether CtBP is present at synapses in *Drosophila*. Similarly, the *Ciona* genome (a urochordate) has a single CtBP gene that lacks the coding sequence for Ribeye (Bradford, Y. and Roberts, W. M., unpublished observations). The simplest evolutionary scenario consistent with the data is that a gene duplication event early in the vertebrate lineage, but after the divergence of urochordates from vertebrates, gave rise to paralogous genes, CtBP1 and CtBP2. The CtBP2 gene then acquired an alternate first exon, which became involved in aggregation of CAZ components (Schmitz, F. *et al.*, 2000) into large structures (ribbons), with important, but largely unknown consequences for afferent synaptic transmission in the eye and ear. Ribeye expression became limited to the small class of ribbon synapses, while CtBP1 continues to be expressed at other synapses. An additional gene duplication gave rise to two CtBP2/ribeye genes in teleost fishes (Wan, L. *et al.*, 2005).

Besides Ribeye, only one other protein, the B16 antigen, has been proposed to be a unique component of all ribbon synapses. This protein is known only as an antigenic epitope (amino sequence: DTYQHPPKDS; Balkema, G. W., 1991; Nguyen, T. H. and Balkema, G. W., 1999). A search of the human genome and expressed sequence tag (EST) databases shows that only one gene, aconitase, contains a nucleotide sequence that codes for this exact amino acid sequence. Aconitase is a transcription regulator and a regulator of iron metabolism, but reportedly is not present in synaptic ribbons (Nguyen, T. H. and Balkema, G. W., 1999). Human CtBP2 and Ribeye contain a sequence (TYxxPP) near the C-terminus that is part of the B16 antigen and thus might bind the B16 antibody, but synaptic ribbons in fish reportedly also bind the B16 antibody (Balkema, G. W., 1991) even though this sequence is entirely absent from their CtBP2 and Ribeye proteins. Thus, the component of the ribbon that binds antibodies raised against the DTYQHPPKDS peptide remains unknown.

There are other proteins that may be unique to ribbon synapses but are not expressed at all ribbon synapses. The α_{1D} calcium channel is found only in hair cells and is essential for normal hair cell Ca^{2+} current, neurotransmitter release, and for hearing (reviewed in Moser, T. *et al.*, 2006a). Most synapses express N, P/Q, or R-type calcium channels, but hair cells express L-type calcium channels (Cav 1.3) formed by this unique splice variant. This channel opens at unusually hyperpolarized voltages (Koschak, A. *et al.*, 2001; Brandt, A. *et al.*, 2003; Rodriguez-Contreras, A. and Yamoah, E. N., 2003; Schnee, M. E. and Ricci, A. J., 2003), which may cause the transmitter release responsible for the baseline action potential rate (i.e., SR) in afferent neurons. Retinal rods express a different L-type calcium channel at ribbon synapses, Cav 1.4 (α_{1F}; Morgans, C. W., 2001).

Another protein that may be unique to ribbon synapses is complexin IV (Pabst, S. *et al.*, 2000; Reim, K. *et al.*, 2006). Based on similarity of complexin I and II, and the ability to rescue synaptic transmission in complexin I/II knockout mice, both complexin III and complexin IV are potential calcium-dependent regulators of synaptic transmission. Complexins I and II are known to bind to the soluble NSF (*N*-ethylmaleimide-sensitive factor) attachment receptor (SNARE) complex that forms the core of the vesicle fusion machinery at many synapses (McMahon, H. T. *et al.*, 1995; Reim, K. *et al.*, 2001; Chen, X. *et al.*, 2002; for a review, see Sudhof, T. C., 2004). Complexins III and IV have both been

described at ribbon synapses in the retina, but only complexin IV was found to be unique to retinal ribbon synapses. It was not reported whether complexins III or IV are present in the ear.

Otoferlin is another protein that may be involved in synaptic transmission by hair cells. This protein was discovered by genetic mapping of familial deafness (Yasunaga, S. *et al*., 1999), and is essential for hearing. The otoferlin gene is large and complex, having 48 exons and many splice variants (Yasunaga, S. *et al*., 2000). It is similar to the FER-1 protein of *Caenorhabditis elegans*, which has been implicated in vesicle membrane fusion (Achanzar, W. E. and Ward, S., 1997). Otoferlin is a candidate to substitute for synaptotagmin as the calcium sensor for transmitter release (Yasunaga, S. *et al*., 2000).

Several other presynaptic proteins, including synapsins and synaptotagmins, are notable by their absence from ribbon synapses (Safieddine S. and Wenthold R. J., 1999; von Kriegstein, K. *et al*., 1999). Syntaxin 1, a component of the core SNARE complex is also missing, replaced by syntaxin 3 (Morgans, C. W. *et al*., 1996).

3.22.4.3 Anatomy of the Synaptic Body: Heterogeneity of Structure

SBs come in a bewildering variety of shapes and sizes. Most synapses have one SB at the synaptic complex, others have two or three (Liberman, M. C. *et al*., 1990). In addition to the typically spherical or ellipsoidal shapes of SBs in hair cells from mice, turtles, frogs, and chicks (Sneary, M. G., 1988; Martinez-Dunst, C. *et al*., 1997; Lenzi, D. *et al*., 1999; Khimich, D. *et al*., 2005), SBs of different geometries and densities have been observed in EM (Giannessi, F. and Ruffoli, R., 1996). In many types of hair cells, the SB appears as a uniformly dense blob, with no internal structure but it also can have a laminar appearance, as in some cochlear IHCs. In old world monkeys the SBs of IHCs nearly always appear ring shaped (Bodian, D., 1980). It is unclear how much of this variability is an artifact of fixation and staining. For example, in the frog retina, synaptic ribbons of a lamellar nature were observed with conventional transmission electron microscope (TEM) thin sections, but were not so apparent when freeze-etching and freeze-substitution methods were employed for tissue preparation (Usukura, J. and Yamada, E., 1987).

SBs vary in size and number among organs, within and between species, as well as among cells within a particular organ. Furthermore, SBs vary in size and shape within individual cells. The dimensions of the SB are typically submicron, ranging from ~200 nm for the shortest principle axis of the ellipsoid SBs in mouse IHCs (Khimich, D. *et al*., 2005) to ~400 nm in hair cells of frog and goldfish sacculus (Gleisner, L. *et al*., 1973; Hama, K. and Saito, K., 1977; Jacobs, R. A. and Hudspeth, A. J., 1990; Lenzi, D. *et al*., 1999). Estimates of the number of ribbon-containing synapses per cell ranged from 10 in mouse cochlear IHCs (Khimich, D. *et al*., 2005) to 85 in the high-frequency hair cells of the turtle papilla (Sneary, M. G., 1988).

Several studies have provided clues regarding the function of SBs in hair cells by demonstrating that the size and number of synaptic ribbons, as well as the numbers of associated calcium channels and SVs, is correlated with the position of the hair cell on the tonotopic axis of the organ. In the turtle papilla, high-frequency cells have three times more SBs, higher vesicle densities near SBs, more calcium channels, and larger calcium currents than do lower-frequency cells (Sneary, M. G., 1988; Art, J. J. *et al*., 1995; Schnee, M. E. *et al*., 2005). Upon depolarization, the high-frequency cells released more vesicles and with faster kinetics. A model of SV trafficking that incorporated all of these data predicted that these differences result in transmission being optimized to the CF of the hair cell (Schnee, M. E. *et al*., 2005). In the papilla of the chick, the diameter of the SB ranged from 120 to 210 nm with increasing CF from apical to more basal positions along the tonotopic axis (Martinez-Dunst, C. *et al*., 1997). These two studies used different experimental approaches to reach a similar conclusion; that the morphology of the SB has influence over the numbers of SVs that are maintained at well-defined positions with respect to the source of calcium influx. SVs close to the center of the AZ may be more responsive to calcium influx if the channels are clustered there (Furukawa, T. and Matsuura, S., 1978; Furukawa, T. *et al*., 1982; reviewed for the case of CNS synapses in Schneggenburger, R. and Neher, E., 2005).

A study in the mammalian cochlea has reported presynaptic morphological correlates of ANF SR and threshold (Merchan-Perez, A. and Liberman, M. C., 1996). Analysis of ultrastructure at the EM level showed that the size and complexity of SBs tended to increase as SR decreased, accompanied by an increase in the total number of SVs clustered at the AZ. These data suggest that the size of the SB has something to do with the regulation of vesicle release that determines the baseline afferent discharge rate

and sensitivity to faint sounds, but the relationship is opposite what is expected based on the prevailing view that the ribbon collects vesicles and conveys them to the release sites. Instead, these data seem to suggest that a larger SB may somehow inhibit SV fusion for weak sounds. Clearly, more work needs to be done to understand the relationship between SB morphology and postsynaptic properties.

3.22.5 The Synaptic Vesicle Cycle in Hair Cells

The basic features of the SV cycle are similar at conventional chemical synapses and ribbon synapses. Both baseline and evoked EPSCs at ribbon synapses require presynaptic calcium influx through channels (Robertson, D. and Paki, B., 2002; Keen, E. C. and Hudspeth, A. J., 2006) and are completely and reversibly blocked by antagonists of the α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA)-type glutamate receptor (Glowatzki, E. and Fuchs, P. A., 2002; Keen, E. C. and Hudspeth, A. J., 2006; Holt, J. C. *et al.*, 2006). The calcium-controlled release of glutamate into the synaptic cleft is quantal, involving exocytosis from SVs that fuse with the plasmalemma and are later retrieved for reuse.

3.22.5.1 Endocytosis

Various routes for vesicle recycling at chemical synapses have been proposed, including two controversial types of fast, local reuse in which the neurotransmitter leaves the SV through a fusion pore without full collapse of the SV membrane into the plasmalemma. In one of these hypothetical fast recycling routes, named kiss-and-stay, the vesicle remains docked to the AZ where it is presumably refilled with glutamate after discharging its contents. In the other, named kiss-and-run, the vesicle undocks and enters a local recycling pool. Slower recycling pathways involve full fusion of the SV with the plasmalemma, followed by clathrin-dependent endocytosis of vesicles or bulk membrane retrieval and reprocessing of SVs either directly or via an endosomal route (reviewed in Sudhof, T. C., 2004). The extent to which each of these processes contributes to the SV cycle under natural physiological conditions remains unclear.

Recent work in the cochlea showed that IHCs may be able to draw upon the vast supply of preformed vesicles present throughout the cytoplasm, and thus may not have to rely on endocytic routes for replenishment of releasable SVs for even the longest stimuli used in many experiments (Griesinger, C. B. *et al.*, 2005). For example, a hair cell that contains 1 million vesicles could, in principle, sustain the exocytosis of 10 vesicles per millisecond for 100 s, although is hard to imagine how the hair cell could accommodate the resultant threefold increase in surface area. Clearly, in the long run endocytosis still must keep pace with exocytosis.

3.22.5.2 Vesicle Mobility

The movement of vesicular membrane through the cytoplasm is an essential step in the SV cycle, except for the case of kiss-and-stay. At conventional synapses, the vesicle-associated phosphoproteins, called synapsins, play essential roles in regulating the movement and clustering of SVs (Rosahl, T. *et al.*, 1995). Studies on hippocampal synapses in synapsin knockout mice have shown that synapsins contribute to the SV cycle by maintaining the reserve pool and the RRP at glutamatergic and GABAergic terminals, respectively (Gitler, D. *et al.*, 2004). The synapsins tether SVs to actin filaments in a phosphorylation-dependent manner (for a review, see Hilfiker, S. *et al.*, 1999).

Synapsins are absent at ribbon synapses, supporting the idea that vesicle clustering and mobilization are different in these cells (von Kriegstein, K. *et al.*, 1999). Recent work in retinal bipolar cells utilized EM, confocal microscopy, and total internal reflection microscopy to demonstrate that cytoplasmic vesicle movement is rapid, random, and not altered by calcium influx or cytoskeletal interactions (Holt, M. *et al.*, 2004, reviewed in Sterling, P. and Matthews, G., 2005). The authors concluded that SVs 2 are highly mobile in bipolar cells ($D = 1.5 \times 10^{-2}\ \mu m\ s^{-1}$), and that random vesicle movement (i.e., diffusion) is sufficient to account for the translocation of vesicles from the large cytoplasmic pool to release sites.

If baseline spike rates in ANFs are due to fusion of SVs, then the diffusion coefficient reported for SVs in bipolar terminals is far too low to support continuous resupply of release sites at mammalian hair cell synapses that sustain SRs of >100 Hz unless some additional mechanism exists to concentrate vesicles in the vicinity of the synapse. Even assuming that diffusion is used only to transport vesicles to the SB, whereupon they are instantly transported to release sites by some other means, and ignoring the

plasmalemma and other barriers that restrict diffusional access to the SB, the maximum steady-state rate at which vesicles can reach the SB by diffusion is

$$F = 4\pi DRC$$

where C is the global concentration of vesicles in the volume. Substituting $D = 1.5 \times 10^{-2}\,\mu m^2\,s^{-1}$, $F = 100\,s^{-1}$, and $R = 100\,nm$, and solving for C yields $C = 5000$ vesicles μm^3, which is more than 50 times the density reported in the nonsynaptic regions of hair cells. This calculation shows that the average concentration of SVs throughout the cytoplasm is too low to continuously supply the SB with vesicles by diffusion unless some additional process operates to maintain the locally high concentration of SVs within a few hundred nanometers of the SB (Lenzi, D. *et al.*, 1999; 2002).

Experiments like these, combined with the observed presence of synaptic ribbons in cell types that support continuous exocytosis have led to the view that the structural and molecular specializations of ribbon synapses assist high rates of sustained vesicle supply to AZs, but crucial questions remain unanswered. For example, data for the refilling of the RRP by vesicles on the SB are indirect; it is still unknown whether or not vesicles actually move on the ribbon.

3.22.5.3 Docking and Priming

In addition to translocation to the AZ, other things must occur before a vesicle is ready for exocytosis. Two important but relatively poorly understood steps are called docking and priming, each of which likely embodies a series of associated events. Docking refers to the placement of a SV in contact with the inner leaflet of the plasma membrane whereas priming refers to the molecular reactions, some ATP-dependent, required to make a vesicle immediately ready for fusion upon calcium influx. It is unclear whether a vesicle must first be docked in order to be primed.

For clues to the relationship between fast exocytosis and docking/priming at ribbon synapses, we look to experimental evidence from retinal bipolar cells. Here the ribbon is plate-like and the anatomical picture of rows of vesicles tethered to both sides of the ribbon led to the model in which the vesicles move along the ribbon to docking sites. One hypothesis is that during a 100 ms strong depolarization all vesicles on the ribbon are depleted via exocytosis. Assuming that this exocytosis requires movement of vesicles along the ribbon to the plasmalemma, several lines of evidence argue against the involvement of ATP-dependent, kinesin-mediated translocation of vesicles to the plasmalemma (Heidelberger, R. *et al.*, 2002). This observation led to the alternative hypothesis that SVs on the ribbon can fuse with each other (reviewed in Parsons, T. D. and Sterling, P., 2003), creating chains that extend to the plasmalemma. This mechanism can account for the large EPSCs recorded postsynaptically at hair cell synapses (see Section 3.22.6.3), and implies that vesicles on the ribbon can be primed and fuse with each other. However the protein Munc13-1, thought to be necessary for priming (Rosenmund, C. *et al.*, 2003), was found to cluster with calcium channels at the plasma membrane and not on the ribbon (tom Dieck, S. *et al.*, 2005), implying that the final priming steps must take place near the membrane.

3.22.5.4 Transmitter Release and Clearance

Glutamate released into the synaptic cleft binds to postsynaptic AMPA receptors (Ruel, J. *et al.*, 2000; Glowatzki, E. and Fuchs, P. A., 2002; Keen, E. C. and Hudspeth, A. J., 2006), causing a depolarization of the postsynaptic membrane and, if the depolarization is sufficient, one or more action potentials. *N*-Methyl-D-aspartate (NMDA) receptor antagonist had no effect on ANF activity, suggesting that they are functionally absent. The pattern of spikes depends on the temporal pattern of neurotransmitter release, the kinetics of AMPA receptor activation, stochastic spike generation, and neuronal refractoriness. Most *in vivo* studies have focused on the firing properties of ANFs in response to pure tones of varying intensities.

If quantal release of neurotransmitter is to accurately reflect the temporal pattern of the sound stimulus, then the chemical signal in the synaptic cleft must rapidly be terminated, which involves uptake of glutamate from the synaptic cleft by excitatory amino acid transporters (e.g., GLAST) in surrounding supporting cells and afferents (Furness, D. N. and Lehre, K. P., 1997; Furness, D. N. and Lawton, D. M., 2003). Voltage-clamp recordings from inner phalangeal cells in the cochlea of normal rats and GLAST knockout mice showed the presence and absence, respectively, of currents produced by these transporters (Hakuba, N. *et al.*, 2000). Normal glutamate reuptake from the synaptic cleft is also thought to be important for the prevention of noise-induced damage to afferent terminals, which can be mimicked by GLAST blockers (Hakuba, N. *et al.*, 2000; Rebillard, G. *et al.*, 2003) and prevented by AMPA receptor blockers.

3.22.5.5 Relating Anatomical and Functional Vesicle Pools

The hair cell's compact shape has proved fortuitous for experimental measurements of synaptic exocytosis by observing the increase in electrical capacitance associated with the increased cell surface that occurs when SVs fuse with the plasmalemma (Figures 6(a)–6(d); Lindau, M. and Neher, E., 1988; reviewed in Nouvian, R. *et al.*, 2006). Because the surface area of a single SV can be estimated, capacitance changes can be translated into numbers of SVs exocytosed, although given the uncertainties in SV diameter and specific membrane capacitance, such calculations are probably only accurate to within a factor of two. These functionally derived SV counts can be compared to numbers obtained with anatomical studies at the EM level in order to test hypotheses about the relationships between the structure and the function of SV pools. The reliability of this technique in accurately monitoring the release of neurotransmitter has been verified by combining capacitance

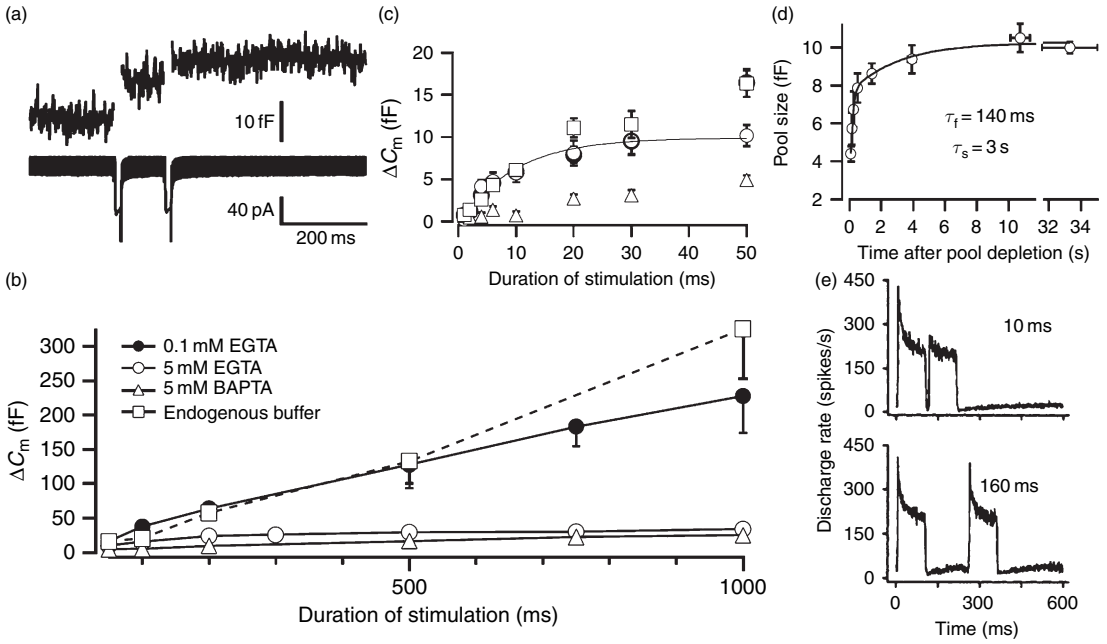

Figure 6 Exocytosis from inner hair cells, recovery from synaptic vesicle pool depletion, and adaptation/disadaptation of auditory nerve fiber responses. (a) Plasma membrane capacitance changes (upper) caused by depolarization-induced synaptic vesicle exocytosis that depends on calcium influx (lower). Two 15 ms depolarizations to the peak of the IV curve for calcium (−15 mV) were separated by 100 ms. Although the calcium currents evoked by the paired pulses were the same, the exocytic response to the first pulse was greater than the response to the second pulse (secretory depression). (b, c) The amplitude of stimulus-evoked capacitance changes is plotted as a function of the duration of the depolarization for different intracellular calcium-buffering conditions. (c) The first 50 ms of (b) at higher temporal resolution. With the cell's endogenous buffer present, the readily releasable pool (RRP) is depleted within the first 10 ms, after which exocytosis continues at a slower rate that is sustained for at least 1 s. The slow calcium buffer (EGTA) of 5 mM abolishes the sustained release while leaving exocytosis of the RRP intact. The fast calcium buffer (BAPTA) of 5 mM inhibits both fast exocytosis of the RRP and the slower component of exocytosis. (d) Strong depolarizations sufficient to deplete the RRP were followed by a second identical stimulus with varying interstimulus intervals as indicated on the *x*-axis. Recovery of the RRP as a function of time after pool depletion has both rapid and slow components. (e) Auditory nerve fiber spike rate *in vivo* as a function of time after sound onset. The sound is interrupted by 10 ms (upper) or 160 ms (lower). During a sound presentation, the spike rate is initially very high followed by two phases of fast reduction in firing rate called rapid and short-term adaptation, with time courses of about 10 and 100 ms, respectively. The 10 ms interruption (upper) is not enough for recovery from rapid adaptation of the spike rate whereas the 160 ms interruption (lower) is sufficient for nearly complete recovery of the initial spike rate. Note the depression of baseline rate and its recovery after sound offset. Panels (a)–(d) are for the mouse: Reproduced with permission from, Copyright (2000) National Academy of Sciences, U. S. A., Moser, T. and Beutner, D., Kinetics of exocytosis and endocytosis at the cochlear inner hair cell afferent synapsis of the mouse. Proc. Natl. Acad. Sci. U S A 97, 883–888. Panel (e) is from the chick: JARO, Vol. 5, 2004, Evidence that rapid vesicle replenishment of the synaptic ribbon mediates recovery from short-term adaptation at the hair cell afferent synapse, Spassova, M. A., Avissar, M., Furman, A. C., Crumling M. A., Saunders, J. C., and Parsons, T. D., Copyright Springer, with kind permission of Springer Science and Buisness Media.

measurements with simultaneous detection of glutamate release in bipolar cells of the vertebrate retina (von Gersdorff, H. *et al.*, 1998).

To estimate the size of the RRP in hair cells, synaptic transmission is first inhibited by hyperpolarization (to fill vesicle pools), then a depolarizing voltage stimulus that maximally stimulates exocytosis is delivered, and the ensuing capacitance increase is observed (Figures 6(b) and 6(c); reviewed in Fuchs, P. A. *et al.*, 2003). Pairs of brief strong depolarizations that evoke maximal calcium currents typically cause paired-pulse depression (Figures 6(a) and 6(d)), implying that the first stimulus partially or totally depletes the RRP, which is refilled more slowly. The size of the RRP can also be measured by applying strong continuous depolarizations of various durations, which evoke continuous calcium currents from the L-type calcium channels at ribbon synapses. Exocytosis of the RRP is seen as an initial rapid increase in capacitance that lasts only a few milliseconds before giving way to a sustained secretory component (SSC) that lasts for seconds (Figure 6(b); Moser, T. and Beutner, D., 2000; Spassova, M. A. *et al.*, 2004; Rutherford, M. A. and Roberts, W. M., 2006). Generally, the size of the RRP measured by change in capacitance is in good agreement with the size of the docked SV pool, as measured by EM, and is smaller than the pool of vesicles on the SB. The presence of a SB and the size of the RRP are both important for normal ANF responses (Khimich, D. *et al.*, 2005; see also Section 3.22.7.2).

The density of vesicles on the SB and in the cytoplasm surrounding the AZ is sensitive to the physiological state of the hair cell before and during fixation (Lenzi, D. *et al.*, 2002). In frog saccular hair cells, prolonged depolarization by high extracellular potassium reduces the density of vesicles on the SB from 79% to 42% of 3D dense-packed, with the greatest reduction occurring in the number of docked SVs in the narrow space between the SB and the plasmalemma. Fixation under resting conditions yielded intermediate values (Lenzi, D. *et al.*, 2002). Whole-cell measurements of SV exocytosis support the notion that all of the docked, SB-associated vesicles can fuse with the plasmalemma within 10 ms (Rutherford, M. A. and Roberts, W. M., 2006). Vesicles in the cytoplasm that are not attached to the SB are also massively depleted by prolonged depolarization (from 10% to 2% of 3D dense-packed in reconstructed volumes within 800 nm perpendicular to the plasmalemma; Figure 4).

Exocytosis of the SSC is slow compared to the RRP (but still a fast resupply rate of hundreds of vesicles per second per AZ), and may indicate the rate at which the RRP is replenished from a recycling pool in the presence of a continuing calcium influx. Dialyzing the cell with the calcium buffer EGTA to inhibit the spread of free calcium away from the AZ (Figures 6(b) and 6(c)) blocked the SSC but not the initial exocytic burst from the RRP (Spassova, M. A. *et al.*, 2004; Moser, T. and Beutner, D., 2000), which suggests that refilling of the RRP is stimulated by long-distance calcium signaling that can be blocked by a slow calcium buffer. Exocytosis of the RRP was inhibited only with the fast calcium buffer BAPTA, as is expected for the case of tight spatial coupling between the release-ready vesicles and the calcium channels (i.e., the RRP docked at the AZ). At present, it is unknown whether the SSC involves vesicles on the SB, other cytoplasmic vesicles that move to the AZ, or possibly even vesicles that are not located at AZs. Experiments that combine capacitance measurements with other techniques to monitor the flow of membrane through the SV cycle will be required to answer such questions.

3.22.6 Physiology of the Hair Cell Afferent Synapse

Precise encoding at the first synapse in the auditory system is absolutely critical for the complete range of behavioral interactions with the acoustic world. To produce a neural representation of the acoustic environment in the CNS, the mammalian cochlea first decomposes complex stimuli into separate frequency components, each of which has an amplitude and a phase. The simplest statement that can be made about sensory encoding in the mammalian cochlea is that the amplitude of the sound at a given frequency is encoded by the spike rate in the ANFs of corresponding CF, while phase and other temporal patterns (e.g., amplitude modulations) are specified by the timing of ANF spikes. Decades of work have produced a wealth of detail about sensory encoding in the auditory system, but much remains to be discovered. The following will barely scratch the surface of what is known. For additional information, the mechanisms underlying the temporal precision of sound coding at the IHC ribbon synapse have been recently reviewed (Moser, T. *et al.*, 2006b).

3.22.6.1 Encoding of Phase

For low-frequency sinusoidal (tonal) stimuli, action potentials in ANFs occur within a narrow time window relative to each cycle of the sinusoid (Anderson, D. J. *et al*., 1970). The discharge of the ANF is said to be phase-locked to the stimulus (Rose, J. E. *et al*., 1967). Phase locking has been observed experimentally in the auditory pathways of mammals, birds, reptiles, amphibians, and fish, and is thought to be an important mechanism for the temporal encoding of low-frequency sound. For example, phase differences between the two ears provide important binaural cues for localizing sounds horizontally (Knudsen, E. I. and Konishi, M., 1978; see Chapter Encoding of Interaural Timing for Binaural Hearing).

Phase locking declines as frequency increases until action potentials in the auditory nerve become nearly random with respect to the stimulus period. The frequency where this transition occurs in the cochlear nerve is generally between 1 and 4 kHz, but it varies among species and even within an individual cochlea. In part, the decline of phase locking with increasing frequency can be attributed to the low-pass filtering of the AC component of the receptor potential by the hair cell membrane (Figure 7). When intracellular receptor potentials were recorded *in vivo* from a guinea-pig cochlear IHC, the receptor potential was quasisinusoidal with the periodicity of the stimulus for low-frequency tones (Palmer, A. R. and Russell, I. J., 1986; Cheatham, M. A. and Dallos, P., 1993). The AC (periodic) component of the receptor potential began to decline at 600 Hz and was not detectable above 3.5 kHz, leaving only a DC (steady) depolarization (Figures 7(a) and 7(b)). The diminution of the presynaptic AC component was mirrored by a decline in postsynaptic phase locking (Figure 7(c)).

Recordings of spike trains in the saccular branch of the eighth nerve in frogs have shown that vibrations at frequencies $\leq$50 Hz evoke a single, phase-locked spike for each cycle of the stimulus (Koyama, H. *et al*., 1982; Christensen-Dalsgaard, J. and Narins P. M., 1993). When expressed as spikes per second, the response thus decreases in proportion to frequency below 50 Hz. Because for low frequencies the depolarizing phase of the hair cell receptor potential may be

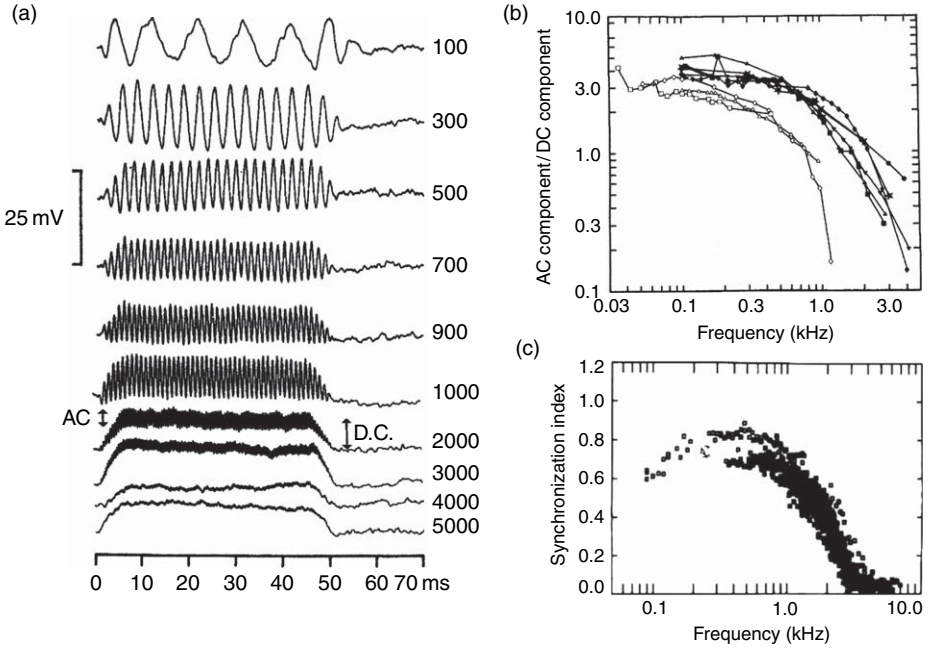

Figure 7 The relationship between receptor potentials in inner hair cells (IHCs) and phase locking in auditory nerve fibers. (a) Intracellular recordings of receptor potentials in one IHC of the guinea-pig cochlea in response to loud (80 dB sound pressure level) tones at the frequency (Hz) indicated by the right side of each trace. The receptor potential has an oscillatory (AC) component and a steady-state (DC) component. The AC component dominates at low frequencies but is almost absent above 3000 Hz. (b) The ratio of AC to DC component across frequency for the receptor potentials from nine different IHCs. (c) The synchronization index (a measure of phase locking to the tonal stimulus) plotted as a function of tone frequency. (Reprinted from Palmer, A. R. and Russell, I. J. 1986. Phase-locking in the cochlear nerve of the guinea-pig and its relation to the receptor potential of inner hair-cells. Hear Res. 24, 1–15, with permission from Elsevier.)

relatively long (e.g., 5 ms for 100 Hz) compared to the duration required for fusion of a single vesicle, the synapse could generate a single spike per cycle if synaptic exocytosis occurred primarily within a narrow time window in response to the onset of each depolarizing phase of a periodic stimulus, and was subsequently suppressed until the next depolarization. This possibility was tested using capacitance measurements as the assay of SV exocytosis (Rutherford, M. A. and Roberts, W. M., 2006). A 30 ms depolarization to −55 mV was interrupted with a return to −80 mV, thus creating a pair of 10 ms depolarizations separated by 10 ms. If the synapse responds primarily to stimulus onset, then the response to the interrupted depolarization is expected be twice the response to a maintained 30 ms depolarization, even though the interposed hyperpolarization reduces the total calcium influx. The total capacitance change in response to the interrupted stimulus was nearly twice as large as the response to the sustained depolarization. The result may reflect the mechanism by which hair cell limits the ANF discharge to a single phase-locked spike per stimulus cycle at low frequencies.

3.22.6.2 Encoding of Frequency

In general, all ANFs phase lock to low frequencies, regardless of their CF. Therefore, the timing of ANF spikes can provide information about the frequency of a low-frequency sound independent of the fiber's CF (Figure 2). For frequencies above 3–4 kHz, the alternative to temporal coding is place-rate coding (Javel, E. and Mott, J. B., 1988), which does not rely upon the temporal (fine timing) pattern of spikes to communicate frequency. In the case of the mammalian cochlea, which performs exquisite mechanical tuning, frequency can be determined from peaks in action potential rates in ANFs that innervate specific CF regions (labeled lines) in the organ of Corti. Therefore, an increase in the mean firing rate of an ANF that originates from a particular place in the organ of Corti is a mechanism for specifying frequency to the brain. Auditory nuclei in the brain stem may use different decoding algorithms for different frequency ranges in order to interpret firing patterns of the auditory nerve.

3.22.6.3 Baseline and Evoked Synaptic Activity

Whole-cell recordings from postsynaptic afferent terminals demonstrated EPSCs (Figure 8) resulting from baseline and evoked SV exocytosis from rat IHCs (Glowatzki, E. and Fuchs, P. A., 2002) and from hair cells of the frog amphibian papilla (Keen, E. C. and Hudspeth, A. J., 2006). In both cases, EPSCs were fast (1–2 ms for the rat, 2–3 ms for the frog) with very rapid onset and exponential decay. Sensitivity to AMPA receptor antagonists provided a functional confirmation of previous *in vivo* and EM studies (Matsubara, A. *et al.*, 1996), showing that the glutamatergic receptor subunits GluR2/3 and 4 are present.

The amplitude distribution of EPSCs recorded under baseline conditions (i.e., extracellular saline with normal concentration of potassium) showed ∼20-fold variation in the rat and ∼10-fold variation in the frog with mean sizes of 190 and 100 pA, respectively (Figure 8). This is remarkable considering that spontaneous glutamatergic EPSCs recorded elsewhere in the CNS are distributed normally with much smaller variation around a quantal size of 20–40 pA.

Presynaptic depolarization via paired whole-cell recordings in the frog, and by perfusion with high-potassium saline in the rat, greatly increased the EPSC rate (Figure 8(a)) while the amplitude distribution remained relatively unchanged (Figures 8(d) and 8(e)). In both preparations, individual small events (miniature EPSCs) were observed, but the amplitude distributions were skewed to larger events for both baseline and evoked EPSCs. For example, in the rat the peak in the amplitude distribution changed from about 18 pA in 5.8 mM potassium (baseline, Figure 8(d), left) to about 36 pA in 40 mM potassium (evoked, Figure 8(e), left), as the mean rate changed from about 1.5 to 27 events per second. Interestingly, the mean EPSC size was slightly less for evoked EPSCs, perhaps due to SV depletion with the sharp increase in EPSC frequency. Combined with the positive shift in the peak of the amplitude distribution, this results in a tightening of the EPSC amplitude distribution (e.g., smaller interquartile range), although the total range remains unchanged (cf. Figures 8(d) and 8(e), left). In both frog and rat hair cells, the larger EPSCs were sometimes multiphasic, but the durations of the larger monophasic events were not appreciably longer than the smaller monophasic events (Figure 8(b), frog; Figures 8(c)–8(e), rat), which suggests that if the large EPSCs are due to the fusion of several SVs, then these fusion events are highly synchronized (reviewed in Parsons, T. D. and Sterling, P., 2003; Singer, J. H. *et al.*, 2004). Two possible mechanisms might explain such multiquantal events. One possibility is that the opening of

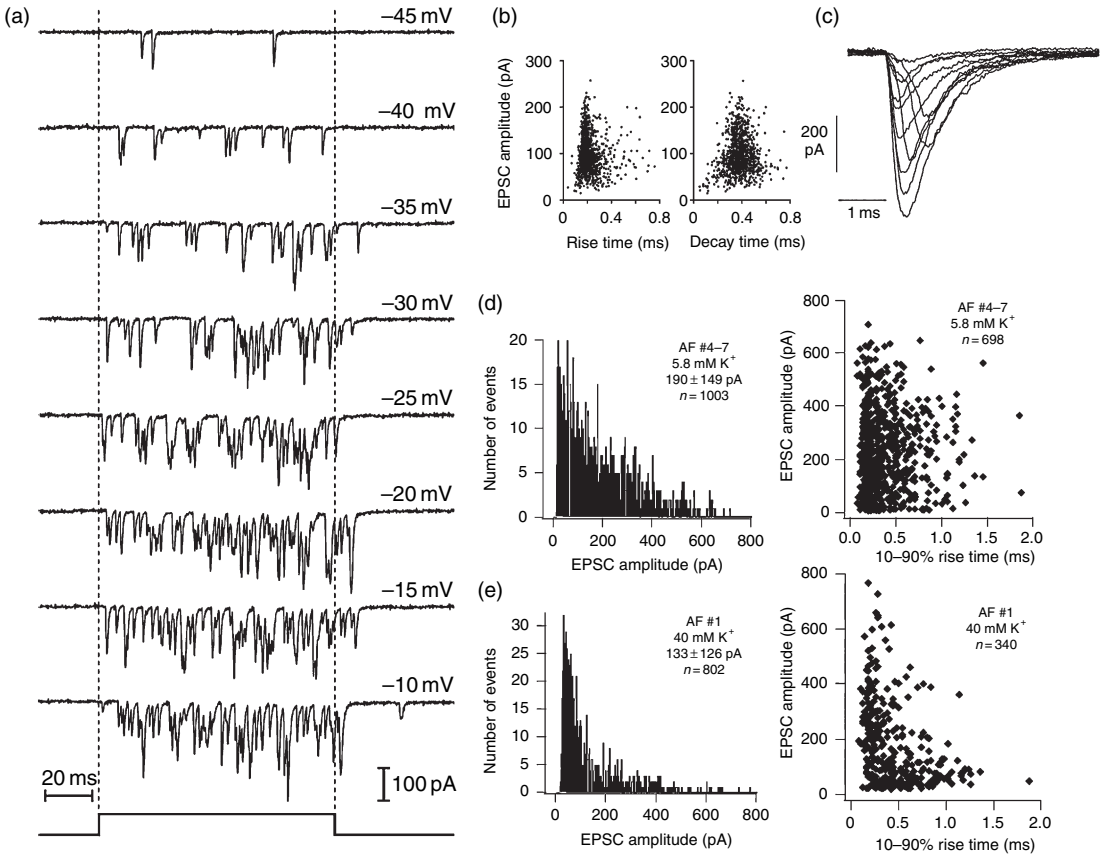

Figure 8 Excitatory postsynaptic currents (EPSCs) in afferent fibers indicate the size and frequency of glutamate release from hair cells. (a) EPSCs recorded in afferent fibers of the frog amphibian papilla while the presynaptic hair cell was depolarized to the voltages indicated at the right of each trace. The predominant effect of depolarization was an increase in EPSC frequency, with little change in EPSC amplitudes. (b) The rise and decay times for baseline EPSCs (frog) are tightly distributed despite a wide range of amplitudes. (c) EPSCs evoked from rat cochlear afferent fibers in response to inner hair cell depolarization by 40 mM extracellular potassium, aligned in time, exhibit a large range in the amplitude of monophasic events. (d, e) Left: EPSC amplitude distributions from rat afferent fibers show the number of events observed in each amplitude bin along the *x*-axis. Baseline EPSC amplitudes from four afferents are shown in (d), evoked EPSC amplitudes from one afferent in (e). The distributions are positively skewed, suggestive of multivesicular release events from individual hair cell active zones. The range of baseline EPSC amplitudes observed in a normal concentration of extracellular potassium (5.8 mM) spans the entire range of EPSC amplitudes evoked by depolarization in high potassium (see text). Mean amplitudes were 190 pA (baseline) and 133 pA (evoked). Right: The relationship between EPSC amplitude and 10–90% rise time is very similar for baseline (d) and evoked (e) events. (a, b) Reproduced from Keen, E. C. and Hudspeth, A. J. 2006. Transfer characteristics of the hair cell's afferent synapse. Proc. Natl. Acad. Sci. U. S. A. 103, 5537–5542; Copyright (2006) National Academy of Sciences, U. S. A. (c–e) Glowatzki, E. and Fuchs, P. A., 2002. Transmitter release at the hair cell ribbon synapse. Nat. Neurosci. 5, 147–154; Copyright (2002) Nature Publishing Group.

a single presynaptic calcium channel, or a few channels that happen to be close together, triggers the synchronized fusion of several nearby vesicles. Another is that several vesicles undergo nonsynchronous fusion with each other, but their contents are not released until one of them fuses with the plasmalemma.

When spikes are present in intracellular recordings from ANFs, the peak EPSP amplitude is obliterated by the action potential that it triggers, but the slope of the initial rise can be used instead to measure the EPSP size. *In vivo* recordings from afferent units in the guinea-pig cochlea demonstrated a range of EPSP slopes (Siegel, J. H., 1992). Similar to the EPSCs recorded *in vitro* and discussed above, the distribution of EPSP slopes was positively skewed, suggesting the existence of synchronous multiquantal release events. Interestingly, nearly all EPSPs that did not occur during neural refractory periods triggered action potentials.

What then is the consequence of multivesicular release to synaptic function? One possibility is that large EPSCs trigger action potentials with less temporal jitter (Anderson, D. J. *et al.*, 1970; reviewed in Fuchs, P. A., 2005), but this leaves open the question of whether there is some value in having a large variance in EPSP amplitude rather than all being equally large. An intriguing possibility has to do with the role of efferent innervation on the input resistance of afferent terminals. The terminal bouton of a type I afferent is typically postsynaptic to both an IHC and an efferent axon (see Chapter Efferent System). Spikes in the efferent axon release transmitter that opens postsynaptic channels, thereby reducing the input resistance of the afferent terminal. The effect of efferent activity may therefore be to reduce the size of the EPSP produced by a given EPSC. Since efferent activity increases in loud environments, the effect may be to render small EPSCs from the hair cell unable to trigger ANF spikes in loud environments. In this case, the wide distribution of EPSC amplitudes associated with multiquantal events may be important for efferent control of ANF firing rate. Similarly, efferent innervation directly onto hair cells is proposed to evoke inhibitory conductances in hair cells during strong stimuli. The expected effect would be a decrease in hair cell depolarization and calcium influx. Since efferent modulation of synaptic activity is expected to be largely absent from *in vitro* preparations, the effects of such inhibition on the EPSC amplitude and frequency in response to varying presynaptic stimulus levels are unknown.

If large EPSCs are due to the fusion of vesicles with each other on the SB before one of them fuses with the plasmalemma, this could be a mechanism to integrate sound amplitude over many cycles while preserving phase locking of glutamate release to the sound waveform. For this to work, the fusion of SVs with each other on the SB would have to be triggered by the relatively small changes in free calcium that are predicted to occur at distances of tens to hundreds of nanometers from the plasmalemma, whereas the fusion of the resulting multivesicular structure with the cell surface membrane would be phase locked to the large, rapid calcium changes that occur close to the presynaptic calcium channels. In favor of this hypothesis, large irregularly shaped structures that appear to be attached to the SB are seen much more frequently at stimulated synapses than inhibited or resting synapses (Lenzi, D. *et al.*, 1999; 2002, Figure 4). Opposed to this hypothesis, the mean EPSC amplitude did not increase following stimulation (Glowatzki, E. and Fuchs, P. A., 2002; Keen, E. C. and Hudspeth, A. J., 2006).

3.22.6.4 Tuning Mechanisms in Hair Cells

Auditory organs of fish, amphibians, reptiles, and birds all show frequency selectivity resulting from the properties of individual hair cells. These mechanisms are different from the frequency tuning seen in the mammalian cochlea, which is the result of the gradient in stiffness of the basilar membrane (acellular) and active mechanical feedback from hair bundle motion and OHC motility (cellular). Our focus will be on tuning in the other four classes of vertebrate animals.

3.22.6.4.1 Frequency-selective augmentation of membrane potential oscillation

In the turtle auditory papilla, there is no apparent frequency tuning extrinsic to the hair cell (i.e., transduction currents are equal over a broad frequency range). Instead, each cell is intrinsically tuned to a different frequency band by a process that has been called electrical resonance. The resonant frequency is determined primarily by the number and kinetics of the cell's calcium-activated potassium channels, voltage-activated potassium and calcium channels, and electrical capacitance (Ricci, A. J. *et al.*, 2000; and reviewed in Fettiplace, R. and Fuchs, P. A., 1999). Each hair cell preferentially amplifies the receptor potential in a frequency band, with peak amplification near the resonant frequency. The tonotopic axis in this organ is generated by the systematic variation of the hair cells' preferred frequencies along the length of the sensory epithelium. Low-frequency cells have low channel density and slower potassium channel kinetics than high-frequency cells. These variations in channel kinetics are caused by differential expression of potassium channel genes and differential splicing of the mRNAs (Jones, E. M. C. *et al.*, 1999). The result is a continuum of resonant frequencies along the papilla. Similar electrical tuning has been studied in the frog sacculus (Armstrong, C. E. and Roberts, W. M., 1998; 2001) and chick cochlea (Correia, M. J., 1992), but there is no evidence of electrical tuning in the mammalian cochlea.

3.22.6.4.2 Synaptic frequency selectivity

Experiments employing capacitance measurements in hair cells typically use very strong depolarizations

that evoke maximal calcium currents in order to measure vesicle pool sizes by depletion. This approach has been very fruitful for understanding vesicle pools, but the stimuli used for these experiments are much larger than *in vivo* receptor potentials, drawing into question the physiological relevance of the evoked exocytosis. A recent study of frog saccular hair cells (Rutherford, M. A. and Roberts, W. M., 2006) used smaller, sinusoidal fluctuations in membrane potential as the voltage-clamp stimulus to mimic the size and frequency of *in vivo* receptor potentials and looked for frequency selectivity downstream of the known mechanical and electrical tuning mechanisms in these cells. Changes in membrane capacitance were measured in response to small sinusoidal voltage changes (±5 mV centered at −60 mV) delivered at 5, 50, and 200 Hz to test the hypothesis that exocytosis would be largest at 50 Hz, the frequency where the sacculus is most sensitive to airborne and groundborne vibrations. Consistent with this hypothesis, exocytosis was twice as large at 50 Hz than at 5 or 200 Hz, even though the total calcium influx was the same at the three frequencies. This preference for 50 Hz disappeared when stronger sinusoidal stimuli (±10 mV centered at −55 mV) were applied, which is reminiscent of other tuning mechanisms that are saturated by large stimuli (e.g., de Boer, E. and Nuttall, A. L., 2000). It is important to note that the ±5 mV sinusoidal stimulus, while small compared to the stimuli used in most voltage-clamp studies, is well above the amplitude of oscillations that occur at sensory threshold (Dallos, P., 1985). The exocytosis in response to the small stimulus at 50 Hz corresponded to the net fusion of 1.7 SV per AZ per stimulus cycle. This amounts to twice the number of vesicles in the docked pool fusing during the 1 s stimulus, and suggests that new vesicles can dock and be primed for release during the stimulus. This synaptic tuning, operating in series with mechanical and electrical tuning, is expected to contribute to the overall tuning of the sacculus, which has been measured by action potential firing rates and sensitivity in afferent axons of the eighth cranial nerve (Koyama, H. *et al.*, 1982; Lewis, E. R. and Narins, P. M., 1985; Yu, X. *et al.*, 1991; Christensen-Dalsgaard, J. and Narins, P. M., 1993). Similar synaptic tuning could contribute to frequency selectivity at other ribbon synapses, particularly in auditory and vestibular organs where synaptic transmission results in phased-locked action potentials in the postsynaptic neuron.

3.22.7 Auditory Nerve Fiber Firing Patterns Mirror Presynaptic Vesicle Pool Dynamics

Until recently, physiological studies of cochlear output have focused on *in vivo* recordings of spike trains in ANFs in response to sound stimuli (e.g., pure tones of varying SPL). Advances in patch-clamp techniques *in vitro*, such as capacitance measurements as a presynaptic assay of SV exocytosis, have allowed more direct comparisons between presynaptic activity and postsynaptic spike trains.

3.22.7.1 Adaptation of the Auditory Nerve Response

Adaptation of ANF responses is thought to be necessary for the peripheral processing of speech (Delgutte, B., 1980). Two types of fast adaptation have been described to explain the reduction in ANF discharge rate following the onset of a sustained acoustic stimulation (Figure 6(e)). These have been called rapid adaptation and short-term adaptation, with durations of approximately 10 and 20–90 ms, respectively. Although the precise time courses can vary by species, SR of the fiber, and sound intensity; both processes are thought to arise from mechanisms downstream of IHC receptor potential *in vivo*, which is not reduced in amplitude during a sustained stimulus (Russell, I. J. and Sellick, P. M., 1978; Holton, T. and Weiss, T. F., 1983). Fast adaptation is thought to involve presynaptic depression (as described below), but not via inactivation of the presynaptic calcium current which shows no significant decline over this time course under voltage clamp (Parsons, T. D. *et al.*, 1994; Moser, T and Beutner, D., 2000; Schnee, M. E. and Ricci, A. J., 2003; Eisen, M. D. *et al.*, 2004).

Fast adaptation of ANF firing and its subsequent recovery seem to be predominantly due to depletion and refilling of the RRP. Recovery from adaptation takes hundreds of milliseconds (Smith, R. L., 1977; Harris, D. M. and Dallos, P., 1979; Chimento, T. C. and Schreiner, C. E., 1991), and this time course is thought to reflect refilling of the RRP. In the chick, using a combination of *in vivo* single unit recordings of ANF activity and *in vitro* patch-clamp recordings of SV fusion, it was found that sound-evoked ANF activity adapted and recovered with similar time courses as RRP depletion and recovery (Figure 6; Spassova, M. A. *et al.*, 2004). After RRP exhaustion,

its recovery was 95% complete after a 200 ms rest period, similar to the time course of recovery from adaptation. In comparison, analogous recovery in retinal bipolar neurons takes about 100 times longer (20 s; von Gersdorff, H. and Matthews, G., 1997). In the mouse IHC, RRP refilling is biphasic, possibly reflecting the refilling of two functionally distinct types of AZs (Moser, T. and Beutner, D., 2000). Differences among AZs in a single IHC could provide the basis for the variable properties of ANFs (Merchan-Perez, A. and Liberman, M. C., 1996). Indeed high- and low-SR fibers exhibit different times needed for recovery from prior stimuli (Relkin, E. M. and Doucet, J. R., 1991) that are a close match to the biphasic refilling of the RRP (Figure 6(d)).

3.22.7.2 The Role of the Synaptic Body in Auditory Nerve Fiber Spike Timing

Computational attempts at predicting psychophysical performance on auditory tasks based on the activity of ANFs have generally concluded that the probabilistic nature of action potentials (the variability of spike timing during repeated presentations of the same stimulus) limits the precision of acoustic information sent to the brain (Mountain, D. C. and Hubbard, A. E., 1996). Upon repeated presentation of a pure tone, an ANF will fire a first spike with variable latency. The variance of first spike latency in mice with a targeted deletion of the gene for the cytomatrix AZ protein Bassoon was increased by a factor of 12 compared to controls (Buran, B. N. *et al.*, 2006). Bassoon is thought to anchor SBs at AZs by interacting with Ribeye (Khimich, D. *et al.*, 2005; tom Dieck, S. *et al.*, 2005); ultrastructural inspection demonstrated a 90% reduction in the number of SBs anchored at AZs. This work suggests that the presence of SBs at release sites helps to reduce the temporal jitter of ANF discharge, and hence improve phase locking.

In the absence of an applied stimulus, the temporal firing pattern of ANFs *in vivo* is often represented as a poison process, but on a short timescale it is more accurately described as a renewal process that is a function of neurotransmitter concentration in the cleft (presynaptic effect) and neural refractoriness (postsynaptic effect), the combination of which causes the firing probability to be depressed for more than 20 ms following a spike (Gaumond, R. P. *et al.*, 1983). Furukawa and co-workers recorded synaptic potentials from afferent units in the saccular branch of the eighth nerve of the goldfish and observed a 20 ms delay in firing upon a decrement in the intensity of tone. They attributed this delay to the time required for SVs to refill the depleted low-threshold release sites between the SB and the calcium channels at the plasmalemma. Furthermore, quantal analysis of the size of EPSPs showed a negative correlation between the amplitude of two consecutive events (i.e., large EPSPs tend to be followed by smaller ones and vice versa). These data support the idea that adaptive rundown of EPSPs is the result of SV depletion (Furukawa, T. and Matsuura, S., 1978; Furukawa, T. *et al.*, 1978).

Additional evidence for the involvement of the SB in maintenance of the functional RRP comes from the Bassoon mutant mice, in which the first phase of exocytosis and the calcium current are both reduced (Khimich, D. *et al.*, 2005). The large reduction of SB-associated docked SVs at AZs in the mutant provides additional support for the contribution of these docked vesicles to the functional RRP measured in capacitance experiments. The reduced calcium current supports previous evidence that calcium channel expression is coregulated with and restricted spatially to SV release sites adjacent to SBs (Martinez-Dunst, C. *et al.*, 1997; Zenisek, D. *et al.*, 2003). Intriguingly, the sustained component of the capacitance rise was relatively intact in the mutant mice compared to the 50% reduction in ANF discharge rate after short-term adaptation to tonal stimuli (Buran, B. N. *et al.*, 2006). One interpretation is that the sustained component in the mutant mice is relatively asynchronous or not properly localized to postsynaptic fibers. In contrast, the sustained exocytosis in wild-type mice is likely to reflect synaptic release as indicated by the massive sustained release measure by EPSCs in high potassium and higher levels of sustained ANF discharge rate *in vivo*. The sound-evoked onset firing rate (before adaptation) and steady-state firing rate (after fast adaptation) were decreased and threshold was increased, in accordance with the reduction of the functional RRP measured presynaptically. In spite of this, the shapes of rate-level functions were normal in the mutants. Indeed a recent modeling study showed that the effect of increasing the maximum number of transmitter quanta held in the immediate store (analogous to the concept of increasing the size of the RRP) is to scale the release rate linearly across the entire dynamic range (Sumner, C. J. *et al.*, 2002).

Work with the Bassoon mutant mouse has shown that the localization of synaptic ribbons to hair cell

AZs is required for transmitter release to be precisely synchronized to the onset of sound at each AZ, which is required for synchronous auditory signaling carried to the brain stem (Khimich, D. *et al*., 2005; Buran, B. N. *et al*., 2006). If simultaneously activated fibers provide input to a single neuron in the cochlear nucleus, then converging synaptic inputs arriving closely in time could be the physiological basis for a coincidence detector to differentiate between baseline activity and stimulus-evoked (synchronous) hair cell afferent synaptic activity. It seems probable that the precise configurations of SBs and their associated cytomatrices at AZs are important for establishing both the sensitivity and the phase relationship of ANF spikes to the sound.

3.22.8 Synapse to Psychophysics

One of the goals of auditory research is to provide an explanation of the behavior of the auditory system based upon the functions of its cellular components and the circuits they make. For example, numerous experiments have examined the ability of the auditory system to detect weak sounds. These experiments have been carried at the level of ANFs, cortical neurons, and behavior, in a variety of mammals, including humans. Recently it has been proposed that the inverse relationship between the duration and the SPL needed to attain a threshold criterion for detection seen at all levels of auditory processing can be explained by the properties of hair cell afferent synapses. One interpretation of these results is that the statistics of individual events, which may correspond to the exocytosis of individual SVs at the afferent synapse, underlies the trade-off between strength and duration for barely detectable sounds (Heil, P. and Neubauer, H., 2003) that is measured in psychophysical experiments of sound perception.

3.23.1 Introduction

The term auditory neuropathy (Starr, A. *et al.*, 1996) was first used to describe a hearing disorder due to altered function of the auditory nerve in the presence of preserved functions of cochlear outer hair cells (OHCs; Starr, A. *et al.*, 1991). The hearing loss has specific features reflecting impairment of auditory temporal processes that are typically unaffected with sensory outer hair disturbances (Zeng, F. G. *et al.*, 1999). The disorder has also been referred to as type I afferent neuron dysfunction (Berlin, C. I. *et al.*, 1993), auditory neuropathy/auditory dys-synchrony (Berlin, C. I. *et al.*, 2003), and neural hearing loss (Rapin, I. and Gravel, J., 2003). We now know that dysfunction of the auditory nerve, having quite similar clinical features, accompanies a variety of disorders acting on the nerve, the inner hair cell, and/or their synapse. We will refer to the disorder as auditory neuropathy and emphasize whenever possible the site(s) of involvement in the auditory periphery. We will review how the varieties of auditory neuropathy are identified, the special psychoacoustic features of the hearing loss, candidate pathophysiological mechanisms, and cochlear and auditory nerve pathologies. We will introduce recent advances in knowledge of molecular organization of cochlear inner hair cell synapses and auditory nerve that suggest some mechanisms likely to be involved in auditory nerve dysfunction.

3.23.2 Testing for Auditory Neuropathy

Auditory brainstem responses (ABRs) are the far-field reflection of potentials arising in the cochlea, auditory nerve, and auditory brainstem pathways during the first 10–15 ms after a transient acoustic signal. These potentials are of small amplitude in humans (<0.5 μV) and their resolution requires averaging brain activity to several thousand acoustic stimuli. Those potentials that are time-locked to the stimuli appear in the averaged ABR whereas potentials that are not sufficiently time-locked to the acoustic signals are attenuated. The averaged ABR is therefore especially sensitive to the temporal pattern of neural discharge in auditory nerve and brainstem auditory pathways.

The ABR has five major components, labeled in sequence by Roman numerals I through V, which are generated by distinct regions of the auditory pathway. The absolute latencies of the components change with signal intensity but the time difference between each of the components remains relatively

constant independent of stimulus intensity (Starr, A. and Achor, J., 1975). Wave I is generated in the distal portions of auditory nerve in the region of the ganglion cells; wave II is generated in the proximal portions of the auditory nerve in the region of its entry into the brainstem; wave III is generated in the region of the ipsilateral cochlear nucleus; waves IV and V are generated bilaterally in the region of the midbrain tegmentum (Starr, A. and Achor, J., 1975; Starr, A. and Hamilton, A. E., 1976; Martin, W. H. *et al.*, 1995; Melcher, J. R. *et al.*, 1996). Thus the ABR components provide a longitudinal view of sequential activities arising from both the auditory nerve and brainstem portions of the auditory pathway.

Cochlear microphonics (CMs) are receptor potentials generated by both inner and OHCs. Since the dominant type of hair cell is outer, one would expect that the amplitude of cochlear microphonics derives predominantly from outer rather than inner hair cells. that can also be identified in the ABR by separately averaging potentials to condensation and rarefaction stimuli to define phase reversed components in the two averages (Starr, A. *et al.*, 1991; Berlin, C. I. *et al.*, 1998). If the condensation and rarefaction stimuli are presented in an alternating fashion, the CMs to each polarity stimulus cancel and do not appear in the ABR average.

Otoacoustic emissions (OAEs) are faint sounds produced by OHCs (Kemp, D. T., 1978; Brownell, W. E., 1984) that can be recorded by a small microphone in the ear canal and provide a measure of mechanical activity (electromotility) of cochlear OHCs.

By combining measures of ABRs, CMs, and OAEs, the site(s) of altered functions can be identified as affecting one or several of the components comprising the auditory periphery including OHCs, auditory nerve, and auditory brainstem structures. At present, there are no physiological measures available for clinical applications that are specific for identifying disorders of inner hair cells (IHCs) or their pre- and postsynaptic functions with auditory nerve.

3.23.3 Clinical Features of Auditory Neuropathy

The ABR was introduced in the 1970s as a screening method to identify auditory impairments in neonates and children (Hecox, K. and Galambos, R., 1974). There were occasional observations that ABRs could be absent even though the subject was subsequently shown to have preserved hearing by behavioral measures (Davis, H. and Hirsh, S. K., 1979; Kaga, K. *et al.*, 1979; Worthington, D. W. and Peters, J. F., 1980; Lenhardt, M. L., 1981). These authors recognized the paradox these findings posed and suggested explanations ranging from technical limitations of the ABR as a test of hearing to the possibility that the abnormal ABRs might reflect a particular kind of peripheral auditory disorder (Kraus, N. *et al.*, 1984).

Special patients can occasionally provide a solution to clinical paradoxes. We examined such a subject (Starr, A. *et al.*, 1991) identified by her teachers as possibly having a hearing problem. Audiological measures showed absent ABRs inconsistent with the mild low-frequency threshold loss. Speech comprehension was impaired and acoustic middle ear muscle reflexes were absent. When ABRs were tested separately to condensation or rarefaction clicks, short latency components appeared that were phased reversed when the two averages were superimposed consistent with their being CMs rather than neural components. OAEs were also present. Figure 1 contains the test results (audiograms, ABRs, CMs, OAEs, and cortical-evoked potentials) for another patient with the same disorder showing a mild threshold elevation (in this example affecting high frequencies), impaired speech comprehension out-of-proportion to the pure tone threshold elevation, a low amplitude and delayed wave V, and preserved hair cell measures of both CMs and OAEs. The test results for a subject with normal hearing are shown for comparison in Figure 1. The results obtained from the patient were consistent with preserved functions of cochlear OHC functions (normal CMs and OAEs) but impaired function of auditory nerve and brainstem. The failure to obtain an averaged ABR was attributed to altered synchrony of neural activity of auditory nerve rather than to a loss of auditory nerve activity because hearing thresholds were only modestly impaired. Auditory cortical-evoked potentials were present suggesting that neural synchrony was still sufficiently preserved to allow an averaged cortical response to be detected. Finally, psychoacoustic studies in this patient (Starr, A. *et al.*, 1991) and subsequently in others (Zeng, F. G. *et al.*, 1999; 2005) summarized below in this chapter revealed that the hearing disorder is indeed relatively specific for auditory percepts dependent on temporal cues (e.g., speech comprehension, gap detection, masking level differences, and low-frequency difference limens) whereas percepts dependent on intensity cues were normal. The disorder appeared

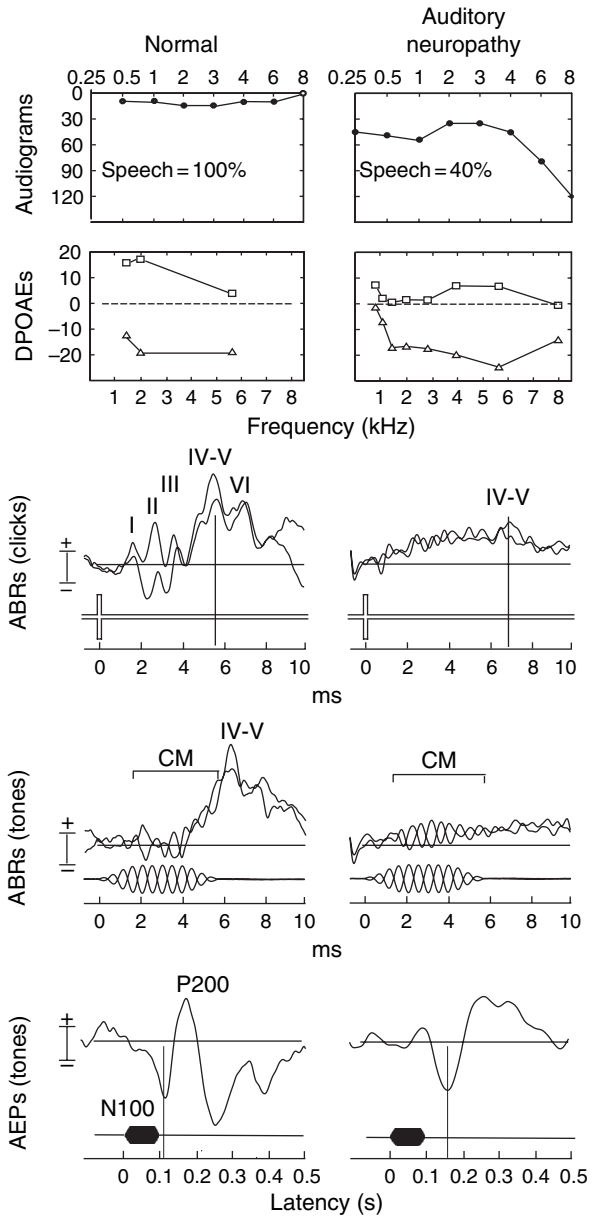

Figure 1 The audiogram (with speech comprehension), distortion product otoacoustic emissions (DPOAEs), auditory brainstem responses (ABRs) to clicks of opposite polarity, ABRs to brief tones (1 kHz) of opposite polarity and auditory cortical-evoked potentials (AEPs) to a 100 ms 1 kHz tone burst are shown for a normal-hearing and auditory neuropathy subjects. The analog stimuli used for the electrophysiological procedures are depicted below the averaged responses. The patient displays a moderate low-frequency threshold elevation that becomes less affected in mid-frequencies, and severe at high frequency (8 kHz). DPOAEs and cochlear microphonics (CMs) are present whereas only a low amplitude delayed wave V can be seen in the click-evoked ABR. The auditory cortical N100 component is present in the patient of delayed latency (160 ms) compared to the N100 in normal hearing subject (N100). Amplitude calibration is 0.25 μV for ABRs and 5 μV for AEPs.

to involve the auditory nerve and/or its synapses with inner hair cells while sparing cochlear OHCs.

Soon, additional subjects with absent ABRs and preserved OAEs and/or CMs were identified. Neurological studies of 11 adolescent and adult subjects with absent ABRs and preserved OHC activity revealed the presence of a peripheral neuropathy in eight, consistent with the presence of a concomitant neuropathy of the auditory nerve (Starr, A. *et al.*, 1996). Subsequently, the temporal bone of a subject with

neural hearing loss and peripheral neuropathy due to a mutation of the *MPZ* gene was examined and revealed marked depletion of auditory neurons with preservation of both inner and OHCs (Starr, A. *et al.*, 2003). The pathological changes in the peripheral sensory nerves and the auditory nerve were similar and consisted of nerve fiber loss (deafferentation) as well as demyelination and incomplete remyelination of the remaining fibers. These results indicate that a hearing loss characterized by a temporal processing disorder, absent ABRs, preserved OAEs and CMs can be a consequence of a neuropathy of the auditory nerve. Both Hallpike C. S. *et al.* (1980) and Spoendlin H. (1974) reported similar temporal bone findings 30 years earlier, in individuals with deafness and hereditary peripheral neuropathies. Satya-Murti S. *et al.* (1980) showed ABRs were absent or severely abnormal in subjects with hereditary neuropathy due to Fredreichs' ataxia and interpreted their findings as reflecting a disorder of the VIII nerve. Thus both a loss of fibers (deafferentation) and/or altered synchrony of nerve impulses in the remaining fibers due to demyelination and incomplete remyelination are likely factors contributing to the temporal processing defects in auditory neuropathy.

Disorders of inner hair cells and their synapses with auditory nerve fibers can also lead to a hearing disorder that is essentially indistinguishable clinically from that accompanying a neuropathy of the auditory nerve. An example of such an inner hair cell disorder occurs with mutations of genes encoding otoferlin (*OTOF*), a putative synaptic protein identified in inner hair cells (Yasunaga, S. *et al.*, 1999; Rodriguez-Ballesteros, M. *et al.*, 2003; Varga, R. *et al.*, 2003). These patients have absent ABRs and in some, preserved OAEs. The hearing loss is severe-to-profound and speech comprehension is a major impairment. Otoferlin belongs to the family of the FER-1 like proteins which are involved in membrane trafficking. Thus the some clinical findings are present with disorders of the nerve and in Otoferlin disorder of inner hair cells. It is likely that a synaptic disorder underlies the hearing loss in these patients, who do not have any evidence of peripheral or other cranial neuropathies.

The findings of auditory neuropathy and Otoferlin inner hair cell disorder (absence of ABRs with preserved OHC functions) are also recognized at high incidence in newborns tested as part of universal infant hearing screening evaluation (Kraus, N. *et al.*, 1984; Doyle, K. J. *et al.*, 1998). It is likely that many of these infants have disorders of both inner hair cells affecting synaptic function and auditory nerves due to metabolic disorders such as hypoxia, hyperbilirubinemia, infections, and prematurity. The infants are typically without clinical evidence of a peripheral neuropathy. In a study of temporal bones of premature infants dying with abnormal ABRs (OAEs were not tested) there were several who showed isolated loss of inner hair cells with preservation of both auditory ganglion cells and OHCs (Amatuzzi, M. G. *et al.*, 2001).

Thus, auditory neuropathy with quite similar physiological and audiological findings can occur as a consequence of pathology of inner hair cell, their synapses, and/or the auditory nerve due to a host of etiologies (Starr, A. *et al.*, 2001a). The common denominators are absence or profound abnormalities of ABRs, absence or profound abnormalities of acoustic reflexes of middle ear muscles and olivocochlear bundle (OCB; Berlin, C. I. *et al.*, 1993), and impaired perceptions dependent on temporal cues. Both the physiological expressions and the types of hearing impairment are remarkably similar whether the disorder is at the inner hair cell, its synapses, or the auditory nerve.

3.23.4 Exceptions to the Criteria for Defining Auditory Neuropathy

The criteria for defining auditory neuropathy have exceptions. First, ABRs are not always absent and a delayed wave V can be defined in approximately 40% of subjects. However, the changes of wave V are beyond those expected for the degree of hearing loss. Second, while it is typical to find absent acoustic middle ear muscle and efferent OCB reflexes, there are some subjects who show the reflexes to be present at elevated thresholds. Third, the impairment of speech comprehension may only be manifest in the presence of noise. Fourth, while OAEs and/or CMs are typically preserved, almost one-third of subjects show OAEs to be absent on retesting. And fifth, while hearing aid amplification is typically without benefit for understanding speech in most subjects, occasionally there are exceptions that do benefit.

The disorder can occur across the age spectrum (Hood, L. J. and Berlin, C. I., 2001; Sininger, Y. and Oba, S., 2001) reflecting a host of etiologies (e.g., hereditary, infectious, and metabolic) and risk factors (hypoxia and hyperbilirubinemia). Almost half of patients cannot be assigned an etiology. The high incidence in neonates and in children at entry to school likely reflects the use of universal auditory screening in neonates (OAEs and/or ABRs) and universal behavioral auditory testing (audiograms) in schools.

The clinical and physiological findings originally used for identifying auditory neuropathy can change over time. Audiograms and speech comprehension decline or remain stationary (Sininger, Y. and Oba, S., 2001). There are documented instances of improvement of ABRs in newborn infants after discharge from the neonatal intensive care unit and even recovery in adults affected with immune disorders acting on nerve fiber (e.g., Guillain-Barré syndrome; Ropper, A. H. and Chiappa, K. H., 1986). OAEs that are present initially may not be obtainable in approximately 30% of subjects (Starr, A. *et al.*, 2001b). CMs appear to persist longer but they too can become attenuated and difficult to detect when patients are over the age of 50 years (Starr, A., *et al.*, 2001b). These findings are consistent with the idea that some forms of auditory neuropathy may be progressive and in others also involve OHC functions.

3.23.5 Pathophysiology of Auditory Neuropathy

The remarkable similarity of electrophysiological findings in subjects with different forms of auditory neuropathy suggests a common pathophysiology independent of site of affliction. Each IHC forms separate synaptic contacts with several afferent fibers. Each of these synapses consists of the presynaptic ribbon-containing active zone and a small (~1 μm) dendritic swelling. Each active zone contains up to 80 $Ca_V1.3$ Ca^{2+} channels and approximately 60 readily releasable glutamate-containing synaptic vesicles, several of which can be released in parallel within milliseconds or less (Khimich, D. *et al.*, 2005). The individual release sites appear to be controlled by few active $Ca_V1.3$ Ca^{2+} channels in nanometer proximity, which activate rapidly upon depolarization and drive vesicle fusion at near saturating speed (Ca^{2+} nanodomain control). The released glutamate rapidly opens postsynaptic alpha-amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA)-type glutamate receptors (Glowatzki, E. and Fuchs, P. A., 2002), which are clustered at the postsynaptic density. Excitatory postsynaptic currents (EPSCs) measured in the nerve terminals display both rapid rise (<0.50 ms) and rapid decay (<2 ms) enhancing nerve spike generation at short latency and the ability to discharge again at short intervals. Synchronous transmission of nerve impulses is optimized by their relatively uniform fiber diameter and corresponding similar conduction velocity. When the nerve impulses reach the first node of Ranvier, conduction is speeded by becoming saltatory.

Mechanisms enhancing temporal precision of auditory information coding and transmission include precise receptor potential generation, rapid Ca^{2+}-channel gating, the nanodomain control of exocytosis, parallel release of multiple vesicles at one active zone, rapid glutamate receptor signaling, and small size of postsynaptic terminal. This precise timing enables synchronization of spiking in fibers driven by one hair cell (same receptor potential). However, there are a host of opportunities for degrading neural synchrony including changes in hair cell mechanics; hair cell metabolic functions; transmitter release and reuptake; receptor sensitivity; nerve terminal nerve spike initiation; and transmission, axonal, and myelin disorders.

If there were a disorder of inner hair cells affecting transmitter release, a synaptic disorder affecting the number or sensitivity of receptor sites, or a disorder of nerve fibers affecting speed of conduction, both the synchrony of discharge and the number of fibers that were active would likely be compromised. We have modeled the general effects of such disorders in Figure 2 (gray spikes) and compared with the normal condition (black spikes). Normally the fibers all discharge at short latency with little variability. However, with a disorder of inner hair cells, the synapse, and/or the nerve fibers, the affected population's response would likely show both altered temporal patterns of discharge and overall amplitude changes. These changes are modeled in Figure 2 by reducing the number of fibers activated by 30%, and introducing in the remaining fibers a variable delay in their latency of discharge. The effects of these alterations impair both temporal synchrony and overall amplitude of response of the population of fibers and are plausible pathophysiological mechanisms accounting for the electrophysiological and psychoacoustic changes.

Figure 3 depicts how neural desynchrony could affect the appearance of the ABR (see details in Starr, A. *et al.*, 1991). The top tracing is of an ABR in which the averaging process always begins 3 ms after each click stimulus. There are five positive peaks present labeled as P1 through P5. Neural desynchrony is simulated in the lower trace by delaying the stimulus in a variable manner from between 3 and 4 ms after the start of the averaging process. Note that components P1 through P5 are markedly attenuated whereas the slow potential shift or pedestal on which the peaks arise is maintained. The attenuation of ABR peaks occurred because the neural events were made to vary in latency to cancel one another

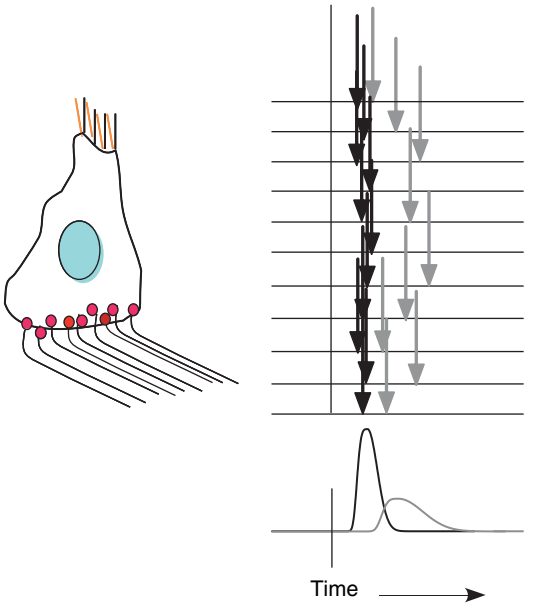

Figure 2 A representation of the patterns of activity of afferent auditory nerve fibers with synaptic connections to an inner hair cell. The onset of a transient stimulus is indicated by the vertical line below. The occurrence of fiber activity in a normally functioning system is represented by black arrows while fiber activity in an abnormal system is represented by gray arrows. The patterns of activity in the two conditions are shown below. The abnormalities of fiber activity that are represented include (a) variable delay in the latency of discharge and (b) absence of a response in 30% of the fibers. Note the short latency and synchrony of the population's response when the system is normal and the delayed latency, temporal dispersion, and reduced amplitude of the population's response when the system is abnormal. We suggest that the pattern of abnormality of activity would be similar whether the disorder were at inner hair cell, the synapse including neurotransmitter release, reuptake and binding to receptor sites, or in the nerve fibers. However, the extent of latency delay and variability as well as in the proportion of fibers that are activated would vary according to the type and extent of the pathological processes.

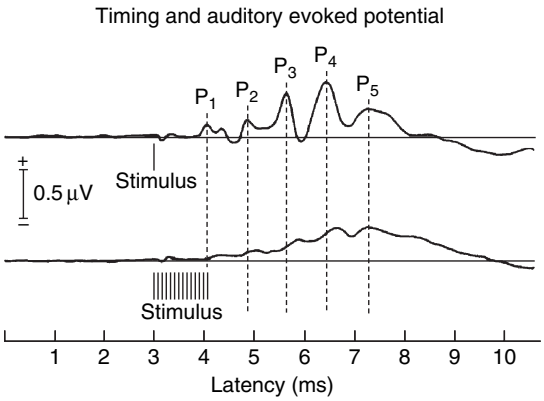

Figure 3 The effect of desynchrony on the ABR. The recordings were obtained from a cat when the stimuli were applied at precisely 3 ms after the onset of the averaging process. There are five peaks identified by the polarity (P for positive) and approximate latency in milliseconds. Another ABR was constituted when the stimulus was applied in a random manner between 3 and 4 ms after the onset of the averaging process. Note the marked attenuation of the five peaks that now appear as small variations in a sustained positive shift.

in the averaging process. The slow pedestal is not affected by the introduction of such a small variation in synchrony. We expect that such an attenuation of ABR components would accompany disorders of inner hair cells, auditory nerve fibers and/or their synapses affecting desynchrony of discharge, and/or a reduction of the number of neural elements activated making the population's response difficult to distinguish from background activity.

We suggest distinguishing the clinical disorder is known as auditory neuropathy by the presumed site of disorder. If the auditory nerve were involved with sparing of the inner hair cells and their synapses, the classification as auditory nerve disorder is appropriate. The finding of concomitant peripheral or cranial neuropathies appears to be the best evidence we have now for inferring the presence of auditory nerve disease. If the inner hair cells and/or the synapses with the auditory nerve were affected with sparing of the auditory nerve, the classification as auditory synaptic disorder is appropriate. The lack of a concomitant neuropathy of peripheral and/or cranial nerves and a positive response to electrical stimulation of the auditory nerve cell bodies is the best evidence we now have to suggest the disorder is distal in the auditory periphery in the region of the inner hair cell and its synapse with auditory nerve terminals. Synaptic disorders could involve alterations in the timing and magnitude of transmitter release and/or the availability of receptor sites on the afferent nerve terminals. There are likely many instances when both auditory nerve and inner hair cells would be affected and the classification of auditory nerve disorder, unspecified may be appropriate.

3.23.6 Psychoacoustic Deficits of Auditory Neuropathy

Auditory psychoacoustics have identified the major perceptual consequences of dysfunction of the auditory nerve (Figure 4). The mean measures of

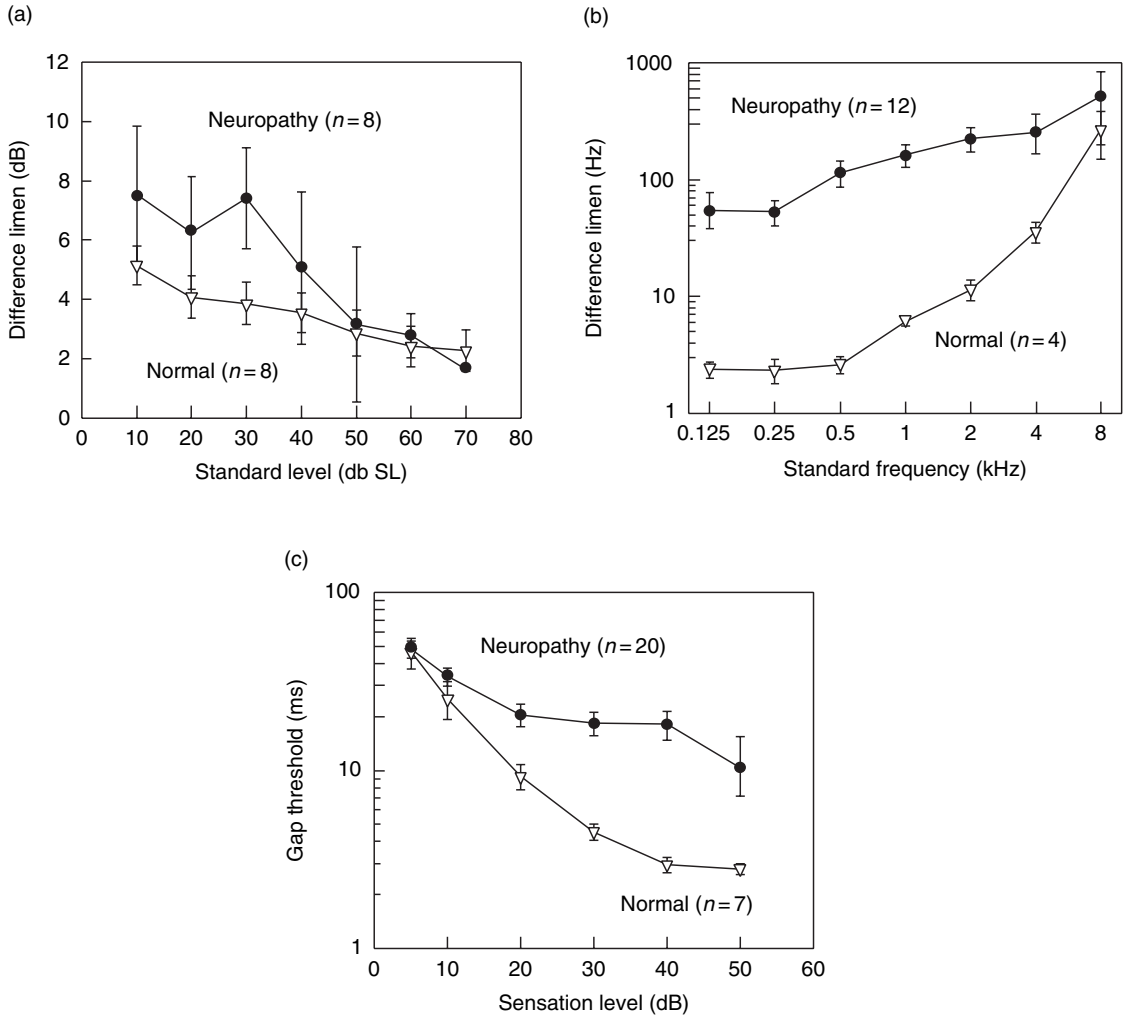

Figure 4 The means and standard errors (vertical lines) of psychoacoustic measures in patients with auditory neuropathy (filled circles) and in normal hearing subjects (unfilled, inverted triangles). The numbers of subjects tested are indicated each panel: (a) intensity discrimination; (b) frequency discrimination, and (c) gap detection. The magnitude of detection limens (DLs) for intensity discrimination was not significantly different between the two groups. In contrast, the difference limens for low frequencies up to 4 kHz were significantly higher in the auditory neuropathy group than the control group. DLs for high frequency (8 kHz) did not differ. Gap thresholds were elevated in auditory neuropathy subjects for intensities that were suprathreshold (>20 dB).

intensity discrimination (Figure 4(a)), frequency discrimination (Figure 4(b)), and temporal gap detection (Figure 4(c)) are plotted for the patients (filled circles) along with normal-hearing controls (unfilled, inverted triangles).

Although the hearing-impaired subjects tended to have greater than normal difference limen in intensity discrimination at low sensation levels, there was no overall significant difference between the affected and normal subjects. In contrast, the auditory neuropathy subjects showed significantly impaired frequency discrimination at low frequencies (125 Hz to 4 kHz) but normal difference limens at the high frequency (8 kHz). Similarly, the hearing-impaired subjects showed significantly impaired gap detection at high sensation levels (20–50 dB) but normal results at low sensation levels (5–10 dB).

Detailed description of other psychoacoustic measures has been obtained to reveal a unique pattern for persons with auditory neuropathy, in which auditory percepts dependent on temporal cues are particularly impaired whereas percepts dependent on intensity cues are preserved (Zeng, F. G. *et al.*, 2005).

Examples of impaired percepts related to temporal cues included pitch discrimination at low frequencies, temporal integration, gap detection, temporal modulation detection, backward and forward masking, signal detection in noise, binaural beats, and sound localization using interaural time differences. Examples of preserved percepts related to intensity cues included loudness discrimination, pitch discrimination at high frequencies, and sound localization using interaural level differences. These results are unique because cochlear or sensory hearing typically affects intensity related percepts (e.g., loudness recruitment) but not temporally related percepts as long as the intensity impairment is taken into account.

Objective measures of gap thresholds can also be defined using cortical potentials evoked by the interruption of a continuous noise with a silent period of different duration. (Michalewski, H. J. *et al.*, 2005). This is particularly relevant for defining temporal functions in children or adult patients who might not be able perform the normal behavioral measures of gap threshold. Figure 5 contains cortical responses to gaps from subjects with normal hearing and two individuals with auditory neuropathy and an elevated gap threshold. Note that an N100 component is clearly present in subjects with normal hearing in response to gaps as short as 5 ms whereas in the patients, N100 appears only with prolonged gap durations that approximate their psychoacoustic detection thresholds.

There were no significant differences between temporal psychoacoustic measures in subjects with a concomitant peripheral neuropathy presumed to also have a disease of the auditory nerve and those without a peripheral neuropathy presumed to have a disease affecting inner hair cells, the nerve terminals, and/or the synapse. Moreover, significant impairment in detecting tonal signals in noise has been observed in neuropathy subjects (Zeng, F. G. *et al.*, 2005). This large excess of masking, along with impaired temporal processing, contributes to the difficulty of understanding speech in noise so frequently observed in neuropathy subjects. We shall note that similar impairment in detecting tonal signals in noise has also been reported in persons who have inner hair cell loss or the so-called dead regions in cochlea (Moore, B. C., 2004). At present, we do not have a means to differentiate between the inner hair cell loss and the nerve loss.

Figure 6 presents possible mechanisms of auditory nerve responses to gaps of short duration when there are normal numbers of nerve fibers responding in a synchronous manner (Figure 6(a)) and the consequences of both impaired synchrony (Figure 6(b)) and reduced numbers of nerve fibers activated (Figure 6(c)). The normal neural response shows a clear spike pattern corresponding to the temporal gap in the stimuli. However, both the reduced neural synchrony and input will diminish this temporal

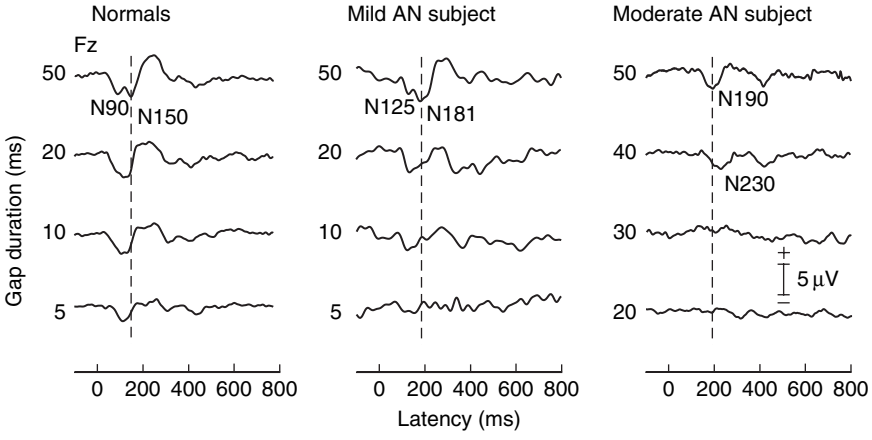

Figure 5 Cortical potentials as objective measure of gap threshold. Scalp-recorded brain potentials to gaps at 50 ms (top traces) and decreasing in duration in subsequent traces indicated on the left of each panel. In normal subjects (psychoacoustic gap threshold was 3 ms) clear N100 components indicated by dashed vertical line can be identified down to 5-ms gaps. In a subject with mild auditory neuropathy (psychoacoustic gap threshold was 8 ms), N100 can be identified at 50, 20, and 10 ms but not at 5 ms. In a subject with a moderate auditory neuropathy (AN; psychoacoustic gap threshold was 30 ms), N100 was delayed and identified at 50 and 40 ms, but not at 30 or 20 ms.

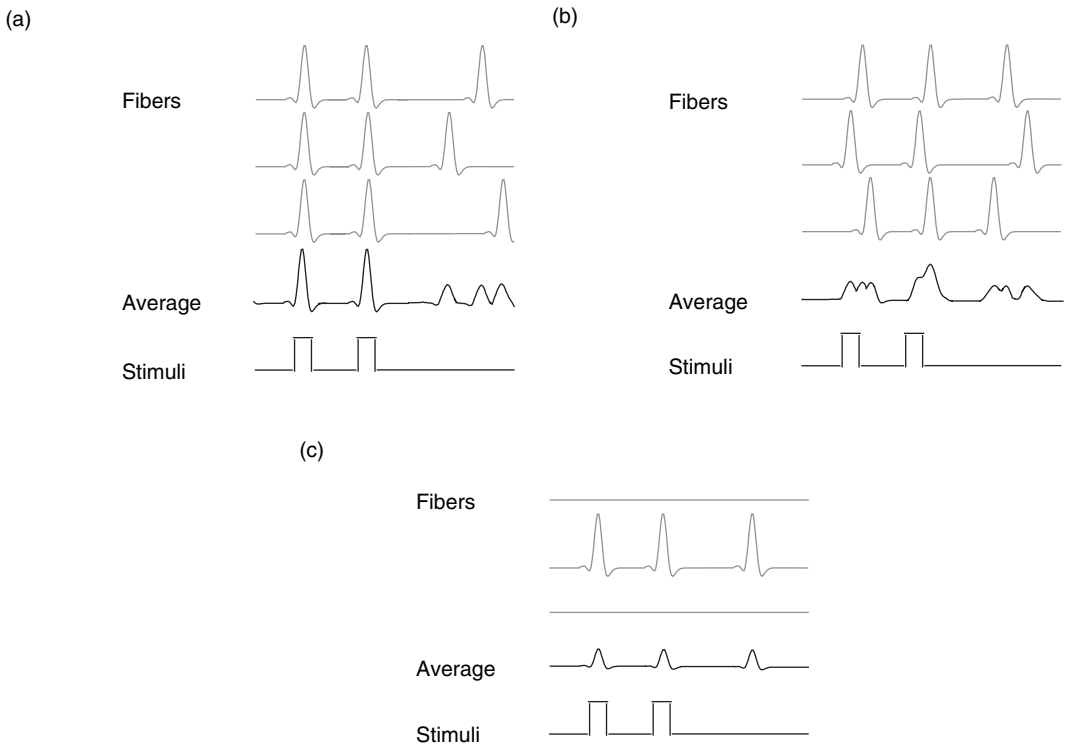

Figure 6 Population of auditory nerve fiber responses of to transient signals separated by a brief temporal gap when there is (a) normal synchrony; (b) desynchronized; and (c) deafferentation but preserved synchrony. Note that the neural representation of the two stimuli and their intervening gap are degraded when there is desynchrony or deafferentation. The condition when both desynchrony and deafferentation coexist would result in further loss of correlation with the acoustic stimuli.

gap at the neural level, making it difficult to discriminate from spontaneous background activity.

At present, we are lacking effective means to differentiate between these two models, as they all tend to show similar audiological, electrophysiological, and behavioral symptoms. Future studies using electric stimulation of the auditory nerve via a cochlear implant (CI) might be able to differentiate these two models, as selective loss of inner hair cells or dysfunctional synapses should not present a significant problem in electric stimulation, which bypasses these structures and activates the neuron's cell body or axon directly.

Clinical management of auditory neuropathy is difficult and not yet standardized. Because of the lack of success with conventional hearing aids, CIs have become the choice of treatment for many clinicians (Shallop, J. K. *et al.*, 2001). The psychoacoustic results suggest that novel features may need to be introduced in hearing aids in order for them to have any chance to help persons with neural hearing loss. One new feature would be to perform modulation expansion as opposed to compression in a typical hearing aid to compensate for the impaired temporal processing abilities. Another feature would be to perform upward frequency shift as opposed to downward frequency shift to take advantage of relatively normal pitch processing at high frequencies in persons with auditory neuropathy.

Individuals with disorders of the inner hair cells or their synapses appear especially likely to benefit from CIs. For instance, auditory neuropathy accompanying mutations of the otoferlin gene (*OTOF*; Rodriquez-Ballesteros, M. *et al.*, 2003; Varga, R. *et al.*, 2003) respond well to cochlear implantation. It is likely that in this disorder there are sufficient numbers of auditory nerve fibers and ganglion cells present capable of responding to electrical stimulation.

Cochlear implantation has also benefited subjects with a dominantly inherited deafness without peripheral nerve involvement (Starr, A. *et al.*, 2004). These subjects initially have absent ABRs and preserved OAEs and CMs. The latter two measures become lost within a few years of onset reflecting an

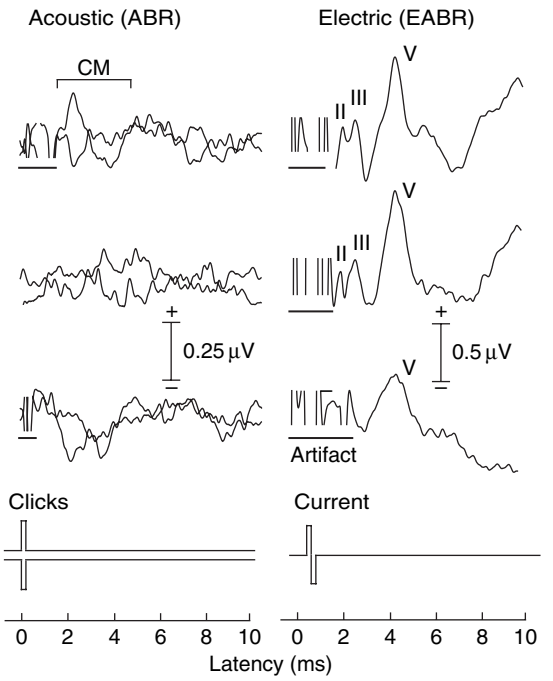

Figure 7 ABRs in three family members with a dominantly inherited disorder producing auditory nerve dysfunction (Starr, A. *et al.*, 2004). Prior to cochlear implantation, ABRs in response to acoustic stimulation do not show neural responses but cochlear microphonics (CM) were identified in one. After implantation electrical stimulation applied through the implant evoked large-amplitude neural components in all three. The artifacts of stimulation are indicated by the horizontal line for both the acoustic and electrical stimulation. Gap detection and speech comprehension improved remarkably following implantation.

involvement of OHCs only later in the course of the disorder. It is likely that the disorder affects inner hair cells/nerve terminals allowing the CI to provide striking benefits. Figure 7 contains ABRs and electrically evoked ABRs (EABRs) from three affected family members before and after implantation. The absence of acoustic ABRs prior to implantation contrasts with the well-developed EABRs after implantation. The subjects' abnormalities of gap thresholds and speech comprehension were also benefited after implantation.

3.23.7 Molecular Mechanisms of Auditory Neuropathy

We will present examples of mice (see Table 1) with genetically engineered defects affecting inner hair cells, synapses, or auditory nerve functions that provide an opportunity to define how specific genes alter auditory functions. Audiological tests of these mutants can identify similarities and differences to auditory neuropathies in humans. There is a particular need to develop both behavioral and objective measures of specific features of the accompanying auditory deficits such as cortical potential measures in response to gaps (Michalewski, H. J. *et al.*, 2005). We expect that characterizing the disorder at the cellular and molecular levels in these mutants may facilitate the development of tests and therapies in human disorders of hearing. The auditory findings on selective examples of gene mutants with various forms of auditory nerve dysfunction are presented below.

3.23.7.1 Inner Hair Cell Channelopathy-Knockout of the Inner Hair Cell $Ca_V1.3$

The molecular identity of the mammalian hair cell Ca^{2+} channel was proven to be $Ca_V1.3$ by a knockout experiment by Platzer J. *et al.* (2000) and Dou H. *et al.* (2004). The Ca^{2+} current of $Ca_V1.3^{-/-}$ inner hair cells is reduced by ~90% in inner hair cells causing a major defect of inner hair cell exocytosis (Figure 8(b); Brandt, A. *et al.*, 2003). $Ca_V1.3^{-/-}$ mice have absent ABRs (Figure 8(c)). Inner hair cells maintain their morphology for at least 2 months after birth but progressively loose their afferent synapses (Nemzou *et al.*, 2006). OHCs at the basilar turn of the cochlear are morphologically preserved for several weeks and produce high-frequency distortion product OAEs. In contrast, OHCs at the apical coil lose their stereovilli and tend to degenerate. There also appears to be an associated reduction of the numbers of surviving spiral ganglion neurons (Glueckert, R. *et al.*, 2003; Dou, H. *et al.*, 2004). A massive exocytosis of transmitter can still be elicited in inner hair cells by artificially increasing the cytosolic Ca^{2+} concentration (Brandt, A. *et al.*, 2003). Together, the results indicate that the lack of inner hair cell $Ca_V1.3$ channels disrupts the coupling of receptor potential and transmitter release. Thus a profound dysfunction of auditory nerve occurs in animals in the neonatal period with a gene defect disabling Ca^{2+} influx into inner hair cell with consequences of disrupting synaptic transmitter release. The disorder is progressive and can also affect the survival of both OHCs and auditory nerve.

Table 1 Animal examples of the variety of auditory nerve dysfunctions

	Primary mechanism	*Animal model (examples)*	*Human disease*	*OAE/CM*	*ABR*	*Morphology*	*Cellular phenotype/ molecular defect*
Disorders of inner hair cells and their synapses	IHC channelopathy	$Ca_V1.3$ KO [a,b,c]		+	Absent	Stereociliar defect of apical OHCs, age-dependent loss of apical OHCs, reduction of SGN	~90% reduction of Ca^{2+} current. Near complete block of IHC transmitter release
Auditory synaptopathy	Defect of presynaptic active zone	Bassoon KO [d]		+	Abnormal	No obvious morphological changes	Defect of synaptic ribbon anchorage at the active zone. Selective defect of synchronous transmitter release
	Inner hair cell vesicle fusion IHC transmitter release	To be generated Otoferlin KO (Roux *et al.*, Cell 2006)	Otoferlin inner hair cell disorders	+	Absent	Normal synaptogenesis, rapid loss of synapses	Major reduction of IHC transmitter release, defect of late step of exocytosis
	Defect of postsynaptic zone	Tubby mouse[e]	Profound prelingual deafness DFNB9				
Disorders of auditory nerve	Mislocalization of ion channels at axon initial segments and nodes of Ranvier	β-4-Spectrin-mutants[f,g]		+	Abnormal	Ultrastructural changes of nerve fibers	Impaired scaffolding of channels and cytoskeletal anchorage
Auditory neuropathy							Impaired nerve conduction
	Demyelination	PMP22-mutants MPZ-mutants[h,i]	Hereditary neuropathies		Abnormal	Demyelination, loss of dendrites, SGN reduction	Impaired nerve conduction due to short internodes, demyelinated axon segments, loss of SGN
	Axon/SGN loss	Dominant-negative erbB4-mutant[j]		+	Abnormal	SGN loss	Loss of axons and SGN

+, present; ABR, auditory brainstem response; CMs, cochlear microphonics; IHC, inner hair cell; KO, knockout; OAEs, otoacoustic emissions; OHC, outer hair cell; SGN, spiral ganglion neurons;

(a) Voltage-gated Ca^{2+}currents in normal (Im: membrane current) (black) and a $Ca_V1.3$-deficient (gray) inner hair cells. There is a major reduction of Ca^{2+} influx in the mutant (~90%). (b) The absence of exocytic capacitance changes (ΔC_m) to paired depolarizations in a $Ca_V1.3$-deficient inner hair cell compared to the normal response. c, ABRs from a 3-week-old wild-type (WT) mouse (black trace) showing normal neural components and the absence neural components in a $Ca_V1.3$-deficient mouse (gray trace).

3.23.7.2 Impaired Inner Hair Cell Transmitter Release

Bassoon is a large matrix protein, which helps to anchor ribbons to the hair cell active synaptic zones. Quantitative assessment of the number of synapse-anchored ribbons of mature mutant mice (stained as green in Figures 9(a) and 9(b)) showed that inner hair cells on average contained one anchored ribbon compared to 10 ribbons in wild-type (WT) animals (Khimich, D. *et al.*, 2005). This reduction in synaptic function is accompanied by abnormal ABRs (Figure 9(c)) showing a marked attenuation and delay of wave I whereas subsequent components were affected only slightly. The thresholds for evoking the ABR were elevated up to 30 dB (Figure 9(d)). OHC activity reflected by CMs and distortion product OAEs were normal. Patch-clamp analysis of inner hair cell presynaptic function revealed a reduced readily releasable pool of synaptic vesicles and a slight reduction of the Ca^{2+} current in ribbon-deficient inner hair cells (Figures 9(e) and 9(f)). Thus, a reduction of ribbon-anchored synapses results in auditory nerve dysfunction reflected by impaired spiral ganglion activation (wave I) without changes in OAEs. The relative preservation of activity arising in brainstem portions of the auditory pathway may indicate that the change of synchrony in the auditory periphery is mild and can be compensated by central auditory mechanisms.

3.23.7.3 Auditory Nerve Ion Channel Displacement

The location of voltage-gated sodium channels in clusters at the nodes of Ranvier in auditory nerves is essential for normal saltatory propagation of action potentials along axons. Beta-4 spectrins are cytoskeletal proteins, which are involved in the positioning and linkage of voltage-gated sodium and potassium channels at the nodes of Ranvier (Bennett, V. and Baines, A. J., 2001). Beta-4 spectrin mutants are also known as Quivering mice because of their abnormal motor behaviors. The alterations in the locations of the voltage-gated channels are shown in Figures 10(d)–10(f). These animals can also have hearing impairments that vary with the mutation. Spontaneous mouse mutants with truncated beta-4 spectrin showed an intriguing correlation of the length of the remaining spectrin protein with the transmission along the auditory pathway (Parkinson, N. J. *et al.*, 2001). In the animals most severely affected only a wave I was present. Auditory studies in less affected mutant animals (Lacas-Gervais, S. *et al.*, 2004) showed auditory thresholds were unaffected (Figure 10(c)) whereas there was progressive delay of ABR peaks consistent with involvement of conduction along the brainstem auditory pathway (Figures 10(a) and 10(b)).

The delay in latency increased at higher stimulation rates and could be consistent with conduction deficits and/or conduction block in the affected fibers.

3.23.7.4 Auditory Nerve Fiber Myelin Disorder

Defects of genes coding for myelin proteins result in hereditary neuropathy (review in Suter, U. and

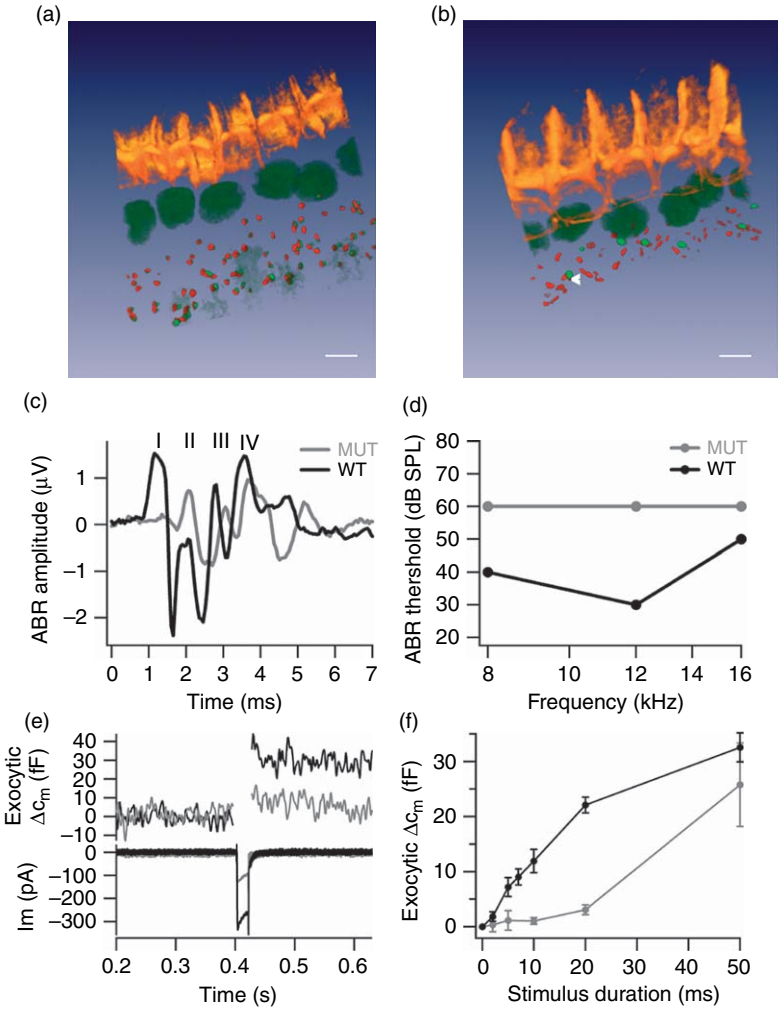

Figure 9 Auditory nerve dysfunction accompanying reduction in the numbers of synaptic ribbons in inner hair cells, the Bassoon mutant. a and b, immunostaining for RIBEYE/CtBP-2 (green): labeling ribbons and nuclei, postsynaptic glutamate receptors (red) adjacent to inner hair cell ribbons. Inner hair cells in mutants (MUT) (a) show fewer ribbon-postsynapstic pairs (arrow) than in wild-type (WT) animals (b). Actin filaments in. . . were labeled with Phalloidin and rendered gold. The apical part of inner hair cell and the adjacent pillar cells are labeled gold. Scale bar: 5 μm. (c) ABR of a representative pair of MUT (gray) and WT (black) mice in response to suprathreshold clicks (80 dB peSPL). Note that wave I was delayed and profoundly attenuated in the MUTs whereas the subsequent waves were only slightly attenuated but delayed in latency. (d) ABR threshold as function of frequency. The MUTs have normal otoacoustic emissions (not shown). (e) Representative Ca^{2+} currents and C_m changes recorded from WT and MUT inner hair cells (20 ms step depolarization). (f) Kinetics of exocytosis constructed from ΔC_m of the same inner hair cells in response to depolarization of varying durations showing depressed response in the MUT. SPL, sound pressure level; Im, membrane current; ΔC_m, exocytic membrane capacitance change.

Scherer, 2003). For example, mutations of the PMP22 gene cause hypomyelination, impaired nerve conduction and consequently neural hearing loss (Verhagen, W. I. *et al.*, 2005) in human Charcot–Marie–Tooth disease (Suter, U. and Scherer, S. S., 2003). Animal models with *PMP22* gene mutations have been described with altered auditory functions. The mutant known as Trembler because of their motor abnormalities shows reduced amplitudes and latency delay of ABR components. There are alterations of myelination of auditory nerve accompanied by a delayed spiral ganglion loss (Zhou, R. *et al.*, 1995a; 1995b). OHC functions have not been defined. These mutant animals have auditory nerve dysfunction due to a nerve disorder affecting myelin.

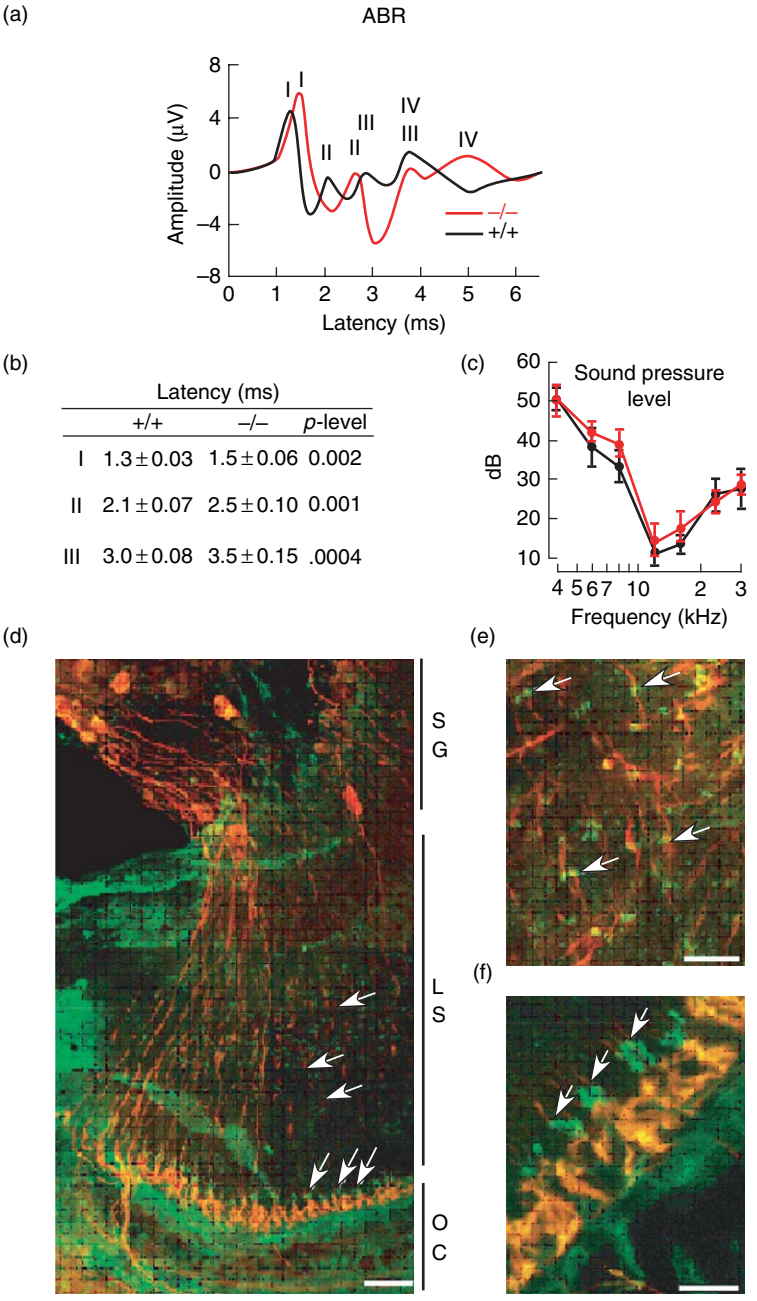

Figure 10 Auditory nerve dysfunction accompanying reduction in the numbers of synaptic ribbons in inner hair cells, the Bassoon mutant. (a) and (b) immunostaining for RIBEYE/CtBP-2 (green): labeling ribbons and nuclei, glutamate receptors (red) adjacent to IHC ribbons. Inner hair cells in mutants (a) show fewer ribbon-postsynapstic pairs (arrow) than in wild type animals (b). The apical part of inner hair cell and the adjacent pillar cells are labeled gold. Scale bar: 5 μm. (c) ABR of a representative pair of mutant (grey) and wild type (WT) (black) mice in response to suprathreshold clicks (80 dB peSPL). Note that Wave I was delayed and profoundly attenuated in the mutant whereas the subsequent waves were only slightly attenuated but delayed in latency. (d) ABR threshold as function of frequency. The mutants have normal otoacoustic emissions. (e) Representative Ca^{2+} currents and C_m changes recorded from WT and mutant IHCs (20 ms step depolarization). (f) Kinetics of exocytosis constructed from ΔC_m of the same IHCs in response to depolarization of varying durations showing depressed response in the wild type.

3.23.7.5 Loss of Spiral Ganglion Neurons

Spiral ganglion neurons may be affected as both a primary and a secondary effect of gene mutations. Recent data demonstrated that the survival of spiral ganglion neurons depends on a complex regulation involving the neuregulin-erbB system and neurotrophin signaling (Stankovic, K. *et al.*, 2004). Their study showed a primary expression of erbB in the supporting cells of the organ of Corti. Disabling the erbB receptor function results in a rapid and ~80% loss of spiral ganglion neurons. Immediately prior to the neuronal loss, downregulation of cochlear neurotrophin-3 expression occurred, which appears to be important for ganglion cell maintenance. The audiological findings are consistent with auditory neuropathy showing absent or profoundly abnormal ABRs and preserved OAEs. Both IHCs and OHCs appear to be little affected. This gene mutation results in auditory nerve dysfunction consistent with loss of spiral ganglion cells without other peripheral or cranial neuropathies.

3.23.8 Conclusions

There has been considerable advance in identifying and characterizing auditory nerve dysfunction in humans. We have highlighted physiological criteria for defining the disorder and identified the diversity of affected structures in the auditory periphery that, when affected, can be accompanied by auditory neuropathy. Psychoacoustic results show that the deficits of auditory nerve dysfunctions primarily affect those percepts dependent on temporal cues. The development of experimental animal models with auditory nerve dysfunction has begun to provide insights into basic molecular mechanisms of the disorders and will hopefully lead to the development of treatment therapies.

Glossary

round-window electrode A metal electrode is positioned near the round window of the cochlea to record cochlear potentials from the auditory nerve and cochlear hair cells, as: auditory-nerve compound action potential (CAP), cochlear microphonic potential (CM), and VIII nerve ensemble background activity.

auditory-nerve compound action potential (CAP) This neural response reflects the summed and synchronous responses of auditory-nerve fibers elicited by clicks or by tone bursts. The amplitude of the N1 wave of the CAP and its latency are the most commonly used measures.

cochlear microphonic potential (CM) It is an alternating potential that resembles the time course of the acoustic stimulus. This potential originates from the outer hair cells of the cochlea.

eighth-nerve ensemble background activity Also known as round-window noise, it is the spontaneous neural activity of auditory-nerve fibers, recorded without auditory stimulation. It is characterized by a frequency peak between 0.5 and 1.5 kHz.

otoacoustic emissions They are low-level sounds emitted by the cochlea, which are believed to originate in outer hair cells. They are classified in spontaneous and evoked otoacoustic emissions. Evoked emissions include transiently evoked and distortion products otoacoustic emissions.

3.24.1 Introduction

The cochlea has highly specialized receptor cells that transform the mechanical energy from acoustic stimuli into changes of cell-membrane electrical potentials. These electrical responses give origin to action potentials that conduct the information through afferent neural pathways to the central nervous system, where auditory perception takes place. Until recently auditory research was mainly focused on the study of transduction mechanisms, afferent neural responses, and psychoacoustics. However, in addition to afferent pathways, the auditory system has conspicuous efferent pathways that project from the central nervous structures to the periphery, as far as to the receptor hair cells from the inner ear, and that can modify the incoming sensory information. This chapter provides a general and comprehensive summary of the current knowledge about the auditory efferent system in mammals, discussing research data obtained in animals as well as in humans. It reviews the main findings on the anatomy, neurotransmission, and physiology of the auditory efferent system and it discusses some of the functions that have been proposed for the efferent system and possible clinical implications.

3.24.2 Anatomy of the Efferent System

The auditory efferent system in mammals originates in the auditory cortex, comprises the inferior colliculus (IC) and the superior olivary complex, and reaches the cochlea through the olivocochlear (OC) fibers. Following the chronological order of anatomical findings in the auditory efferent system, this section first reviews the extensively studied OC efferent system and then the more recently discovered cortico-cochlear connections.

3.24.2.1 Olivocochlear Anatomy

Inner-ear efferent fibers are part of a centrifugal pathway, known in vertebrates as the octavolateralis efferent system, which originates in a group of neurons located in the brainstem and terminates in the hair cells or the eight-nerve ganglion cells of auditory and vestibular organs in mammals and birds, and in the hair cells of the lateral line in fish. In mammals, the brainstem neurons giving origin to auditory and vestibular efferent fibers are completely separated (Simmons, D. D., 2002).

Rasmussen G. L. (1946) was the first to identify in the cat a group of efferent fibers that originate in the ventral brainstem, at the medial region of the superior olivary complex. These fibers that constitute the crossed olivococlear bundle cross at the floor of the fourth ventricle and reach the contralateral cochlea. In a later work (Rasmussen, G. L., 1960), he described a second group of thin fibers that originate in the same region and project to the ipsilateral cochlea, known as the uncrossed OC bundle.

Afterward, using neuronal retrograde tracers Warr W. B. (1975) elucidated the central origin and

the distribution of the crossed and uncrossed OC bundles in the cat. From this and other studies using anterograde tracers (Warr,W. B. and Guinan, J. J., 1979) emerged a new classification of the OC fibers, in which according to their central origin in the brainstem they were separated into: medial OC (MOC) fibers and lateral OC (LOC) fibers. The MOC fibers correspond to large diameter, myelinated axons from neurons located in the medial region of the superior olivary complex, whereas the LOC fibers are thin, unmyelinated axons from small neurons located in the lateral region of the superior olivary complex (Figure 1).

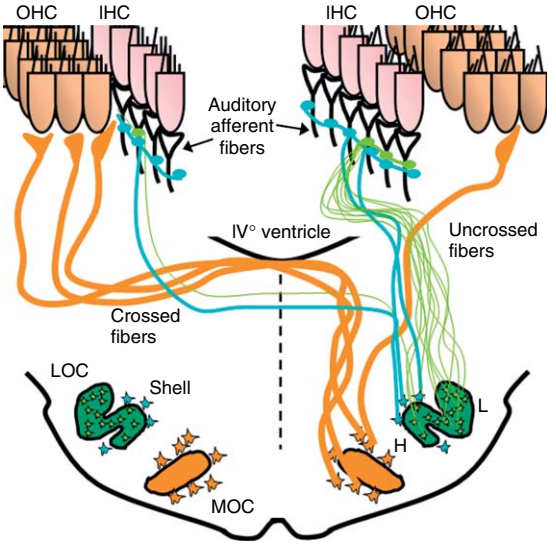

Figure 1 Illustration of the olivocochlear (OC) anatomy. Three different groups of efferent neurons have been identified in the superior olivary complex: (1) intrinsic lateral olivocochlear (LOC) neurons (green), (2) shell neurons from the lateral superior olive (light blue), and (3) medial olivocochlear (MOC) neurons from the medial superior olive (orange). MOC neurons have thick and myelinated axons that mainly project to the contralateral cochlea and make synapses with OHCs. LOC neurons and shell neurons project mainly to the ipsilateral cochlea and make synapses with afferent auditory-nerve fibers. Shell neurons originate in the periphery of the LOC nuclei, and their projections bifurcate to the base and apex of the cochlea. LOC intrinsic neurons are the largest component of the OC system and emerge from the LOC nuclei themselves. LOC axons project unidirectionally to the apex or base of the cochlea. Neurons located in the LOC medial limb project to the base of the cochlea (H: high frequencies), whereas those located in the lateral limb project to the apex (L: low frequencies). Differences in the distribution of OC neurons among mammals can be found in Table 1 (OHC: outer hair cell; IHC: inner hair cell).

These two bundles of OC efferents, besides their different origin, project to different targets in the cochlea. The MOC fibers project mostly contralaterally, making synaptic contact with the three rows of outer hair cells (OHCs), while LOC fibers project mostly ipsilaterally, making synaptic contact with radial afferent auditory-nerve fibers beneath inner hair cells (IHCs; Guinan, J. J., Jr., 1996).

In the following sections the anatomy and neurotransmitters of the medial and lateral OC systems are reviewed separately. For further information in the anatomy and physiology of these systems see Guinan J. J., Jr. (1996) or in cochlear neurotransmitters see Eybalin M. (1993).

3.24.2.1.1 Medial olivocochlear anatomy

MOC fibers emerge from the ventral nucleus of the trapezoid body, and in some species (cats and guinea-pigs) also from the superior periolivary nucleus. In the mature mammalian cochlea, MOC fibers make direct synaptic contact only with OHCs; however, during development, immature IHCs also receive transient innervation from MOC efferents that disappears in later developmental stages (Simmons, D. D., 2002). Although there are differences in the distribution of efferent fibers among species, in all of those studied, most of the MOC fibers cross to the contralateral cochlea through the floor of the fourth ventricle (Table 1). In cats, crossed MOC fibers project mainly to the more basal turns of the cochlea, while uncrossed MOC projections are largest in the center of the cochlea (Guinan, J. J., Jr., 1996). In contrast, the largest MOC projections in mice are directed toward the middle of the cochlea, a location that in this species corresponds to characteristic frequencies around 10 kHz (Maison, S. F. *et al.*, 2003a). Another species-specific difference in efferent innervation is that the MOC synaptic terminal area in cats is four times larger for the first row than that for the third row of OHCs (Liberman, M. C. *et al.*, 1990), whereas in mice there is no gradient of MOC innervation across OHC rows (Maison, S. F. *et al.*, 2003a). In addition to their well-studied cochlear projections, MOC neurons in various species also send axon collaterals to the ventral cochlear nucleus and the vestibular nuclei (Brown, M. C. *et al.*, 1991; Brown, M. C., 1993; Horvath, M. *et al.*, 2000).

An analysis of the anatomy of single MOC neurons performed in selectively labeled axons in rats demonstrated great morphological diversity of MOC neurons, which was evident at the organ of Corti in the number of tunnel-crossing fibers (1–15) and of

Table 1 Species differences in the distribution of olivocochlear efferent fibers

	Medial olivocochlear system (MOC)		*Lateral olivocochlear system (LOC)*			
			Intrinsic LOC		*Shell LOC*	
Species	*Number of neurons*	*Percentage of contralateral fibers*	*Number of neurons*	*Percentage of ipsilateral fibers*	*Number of neurons*	*Percentage of ipsiateral fibers*
Chinchilla (Azeredo, W. J., *et al.*, 1999)	280	80% contralateral	787	99% ipsilateral	101	70% ipsilateral
Rat (Vetter, D. E. and Mugnaini, E., 1992)	316	60% contralateral	619	100% ipsilateral	111	95% ipsilateral
Cat (Warr, W. B., *et al.*, 2002)	549	75% contralateral	769	87% ipsilateral	251	75% ipsilateral
Hamster (Sanchez-Gonzalez, M. A., *et al.*, 2003)	80	75% contralateral	164	97% ipsilateral	65	80% ipsilateral
Guinea-pig (Robertson, D., *et al*., 1987)	543	69% contralateral	690 LOC fibers (99% ipsilateral)			
Mouse (Campbell, J. P. and Henson, M. M., 1988)	164	75% contralateral	311 LOC fibers (99% ipsilateral) (around 30 shell neurons, suggested by Darrow, K. N. *et al*., 2006a)			
Human (Arnesen, A. R., 1984)	360 myelinated fibers (MOC)		1005 unmyelinated fibers (LOC)			

synaptic boutons contacting OHCs (Warr,W. B. and Boche, J. E., 2003). According to their pattern of axonal branching within the cochlea, MOC neurons were sorted into two subtypes: a more common sparsely branched and a quite rare highly branched. In the limited sample of MOC axons analyzed in that study all highly branched fibers projected ipsilaterally and innervated short spans of the cochlea.

3.24.2.1.2 Lateral olivocochlear anatomy

The unmyelinated axons of the lateral OC system originate from two subgroups of efferent brainstem neurons: intrinsic and shell LOC neurons (Figure 1; Vetter, D. E. and Mugnaini, E., 1992). The intrinsic LOC neurons are small neurons located within the lateral superior olivary nucleus that project almost exclusively to the ipsilateral cochlea and have dendrites restricted to the nucleus. Intrinsic neurons have a coarse tonotopic distribution in the lateral superior olive (LSO); as neurons located in the lateral limb project to the cochlear apex and those located in the medial limb project to the base (Robertson, D. *et al*., 1987). In contrast with the intrinsic neurons, shell LOC neurons are a small group of large neurons that surround the LSO and project mainly to the ipsilateral cochlea (Vetter, D. E. and Mugnaini, E., 1992). Shell neurons have extensive dendrites that reach into the lateral superior olivary nucleus and probably make contact with other brainstem nuclei. In the rat, shell neurons, like MOC neurons, send axon collaterals that innervate the ventral cochlear nucleus, whereas intrinsic LOC neurons do not project into the ventral cochlear nucleus (Horvath, M. *et al*., 2000).

Based upon the patterns of cochlear innervation in the guinea-pig, LOC axons have been classified into two groups (Brown, M. C., 1987). The largest group of LOC fibers runs unidirectionally (either apically or basally), usually less than 1 mm, in a spiral path within the cochlea and make discrete terminations with synaptic contacts beneath IHCs, while the smallest group of fibers runs bidirectionally in the cochlea, forming axonal swellings throughout a more extended spiral course. A later study also found two types of LOC axons in the rat and showed that axons with focal terminal patterns beneath IHCs

corresponded to intrinsic neurons, whereas those with diffuse terminal patterns corresponded to shell neurons (Warr, W. B. *et al.*, 1997; Warr, W. B. and Boche, J. E., 2003). Although, it is known that lateral OC fibers make synaptic contacts with the dendrites of afferent auditory neurons, just beneath their synapses with the IHCs, it is not clear yet whether these efferent synapses correspond to either one or the other or to both types of LOC axons. Lateral efferents have also been reported to make sporadically synapses directly onto the IHCs (Liberman, M. C., 1980; Liberman, M. C. *et al.*, 1990).

3.24.2.1.3 Medial olivocochlear neurotransmitters

It is well established that the main neurotransmitter of the MOC efferent system, that makes synaptic contact onto OHCs, is acetylcholine (ACh; Eybalin, M. 1993). In some species, there is also evidence that a subset of MOC neurons release gamma-aminobutyric acid (GABA) and calcitonin gene related peptide (CGRP) (Raphael, Y. and Altschuler, R. A., 2003).

Acetylcholine activates a nicotinic receptor located in the basolateral membrane of the OHCs, which has only recently been identified. Elgoyhen A. B. *et al.*, 1994 and collaborators isolated and characterized $\alpha 9$, a new member of the nicotinic ACh receptor subunit gene family, which injected in Xenopus oocytes expressed a homomeric receptor-channel complex. This ion channel, as the other members of the family, is permeable to Na^+ and Ca^{2+} and is activated by acetylcholine. The $\alpha 9$ nicotinic receptor displays unusual pharmacological properties, as it is blocked by nicotinic as well as muscarinic antagonists. *In situ* hybridization studies in the rat show that the $\alpha 9$ nicotinic receptor is expressed in only a few regions of the brain and in the hair cells of the cochlea, both in IHCs and OHCs. Based on this information, the $\alpha 9$ nicotinic receptor was postulated as a candidate for efferent transmission in the cochlea. However, there were still some differences between the biophysical properties of the heterologous expressed homomeric $\alpha 9$ nicotinic receptor and those of the native cholinergic receptor from isolated OHCs. In a later study, Elgoyhen A. B. *et al.* (2001) found another α nicotinic subunit, the $\alpha 10$, which in the adult rat is only expressed in OHCs. Their data show that a heteromeric $\alpha 9/\alpha 10$ nicotinic ACh receptor presents pharmacological and biophysical properties indistinguishable from those of the native cochlear hair-cell receptor. Recent studies in a heterologous expression of $\alpha 9$ and $\alpha 10$ subunits with different mutations in Xenopus oocytes (Plazas, P. V. *et al.*, 2005) suggest that the native $\alpha 9/\alpha 10$ nicotinic receptor is constituted by a pentamer with a $(\alpha 9)_2(\alpha 10)_3$ stoichiometry (Figure 2). For a review in nicotinic acetylcholine receptors in the auditory efferent system, see Lustig L. R. (2006).

There is evidence in mice and guinea-pigs that a subset of MOC fibers releases GABA (Fex, J. *et al.*, 1986; Maison, S. F. *et al.*, 2003a) and CGRP (Safieddine, S. and Eybalin, M., 1992). The presence of GABA and glutamic acid decarboxylase in efferent endings has been shown by inmunocytochemistry, and $GABA_A$ receptors have also been detected in the basolateral domain of OHCs by monoclonal antibodies against α and β subunits of the $GABA_A$ receptor (Plinkert, P. K. *et al.*, 1989; 1993; see also Eybalin, M., 1993). These results, obtained in the guinea-pig cochlea, show a tonotopical distribution of gabaergic fibers and $GABA_A$ receptors, with a predominant presence in the upper cochlear turns. This tonotopical arrangement of gabaergic efferent fibers seems to be opposite to that of cholinergic fibers which are primarily located in the more basal regions of the cochlea (Plinkert, P. K. *et al.*, 1993). In contrast, in mice OHC efferent innervation presents a density peak, similar for acetylcholine, GABA, and CGRP markers, in the central cochlear region (near 10 kHz) and lower values of density in the apical and basal regions (Maison, S. F. *et al.*, 2003a). Furthermore, in mice near 100% co-localization between the three neurotransmitters has been found (Maison, S. F. *et al.*, 2003a), whereas in guinea-pigs only a subset of MOC cholinergic fibers co-localizes for ACh and CGRP (Safieddine, S. and Eybalin, M., 1992) and another subset co-localizes for ACh and GABA (Fex, J. *et al.*, 1986).

3.24.2.1.4 Lateral olivocochlear neurotransmitters

Several neurotransmitters and neuromodulators are known to be released by the LOC system: Acethylcholine, GABA, dopamine, dynorphines, enkephalin, and CGRP (Eybalin, M., 1993), and some of them have been shown to co-localize in LOC neurons. An early work demonstrated in cats that most LOC neurons stained with retrograde tracers (injected into the cochlea), also co-stained with acetylcholinesterase (AChE) (Warr, W. B., 1975). Another work using inmunohistochemistry, in cats and guinea-pigs, found that lateral efferent fibers beneath IHCs exhibited enkephaline-like

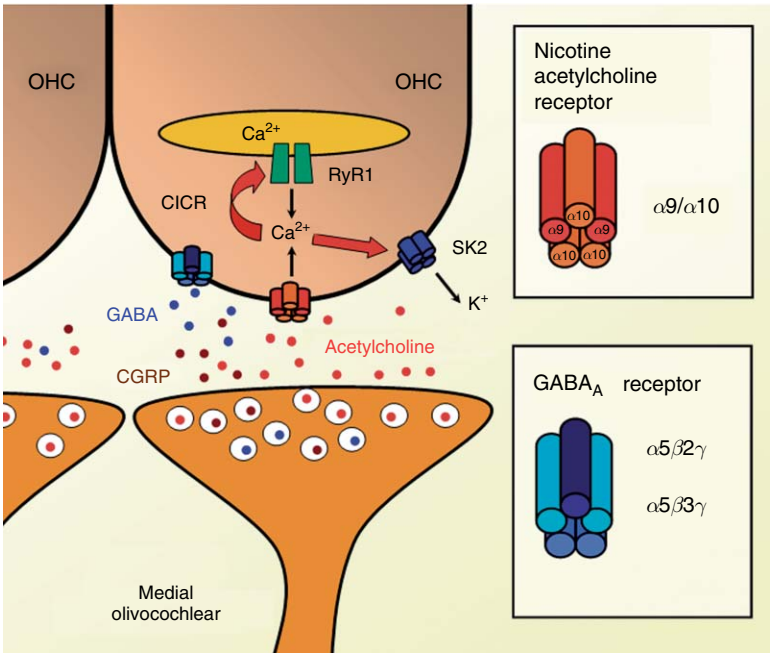

Figure 2 Medial olivocochlear (MOC) synapses with OHCs. The main neurotransmitter released by MOC fibers is acetylcholine that in mice co-localizes with GABA and CGRP (Maison, S. F. *et al.*, 2003a). The opening of $\alpha 9/\alpha 10$ acetylcholine receptors generates an inward Ca^{2+} current in OHCs. An outward current through small-conductance Ca^{2+}-activated K^+ channels (SK2) hyperpolarizes OHCs. It is also postulated that the opening of acetylcholine receptors produces a Ca^{2+}-induced Ca^{2+} release (CICR) from an intracellular cistern through ryanodine receptors (RyR 1). Inset panels on the right show the putative conformations of the pentameric $\alpha 9/\alpha 10$ acetylcholine receptor, and of the GABA receptor at the mouse cochlea (Plazas, P. V. *et al.*, 2005; Maison, S. F. *et al.*, 2006). OHC, outer hair cell.

reactivity (Fex, J. and Altschuler, R. A., 1981). Later, by means of double and triple inmunofluorescence co-localization techniques it was demonstrated, in guinea-pigs and rats, the presence of extensive co-localization of ACh, dynorphines and enkephalines (Abou-Madi, L. *et al.*, 1987) and of ACh, GABA, dopamine, CGRP and enkephaline in most lateral efferent neurons (Safieddine, S. *et al.*, 1997). In contrast, Darrow K. N. *et al.* (2006a) using inmunostaining for tyrosine hydroxylase (dopamine marker) and vesicular acetylcholine transporter in mouse cochleae showed little co-localization of both neurotransmitters in axon terminals beneath IHCs. Consistently, they found that in the brainstem most dopaminergic neurons are distinct from cholinergic neurons (Figure 3). Their results also suggested that in mice the bulk of the lateral efferent fibers reaching the cochlea are cholinergic and only 10–20% of them are dopaminergic (tyrosine-hydroxylase positive).

Acetylcholine released by OC lateral efferents probably activates cholinergic receptors composed by $\alpha 6$, $\alpha 7$, and $\beta 2$ subunits (Morley, B. J. *et al.*, 1998) that depolarize afferent auditory-nerve fibers and enhance glutamatergic transmission from IHCs (Felix, D. and Ehrenberger, K., 1992). Recent studies using inmunocytochemistry in guinea-pig cochlea have established the presence of dopamine transporters in the lateral efferent fibers below IHCs and in the inner spiral bundle (Ruel, J. *et al.*, 2006) and also the presence of D1 receptors in the spiral ganglion neurons and in the afferent nerve endings beneath IHC synapses (Niu, X. and Canlon B., 2006).

In the brainstem, dopaminergic neurons are mainly located surrounding the LSO and they probably correspond to the shell neurons (Vetter, D. E. and Mugnaini, E., 1992), while AChE stained neurons are located within the LSO nucleus, corresponding to LOC intrinsic neurons (Darrow, K. N. *et al.*, 2006a). In a recent study combining intracochlear injections of a fluorescent retrograde tracer and inmunofluorescent staining of tyrosine hydroxylase in the guinea-pig, Mulders W. H. and Robertson D. (2004) succeeded in demonstrating that dopaminergic neurons from the LSO project to the

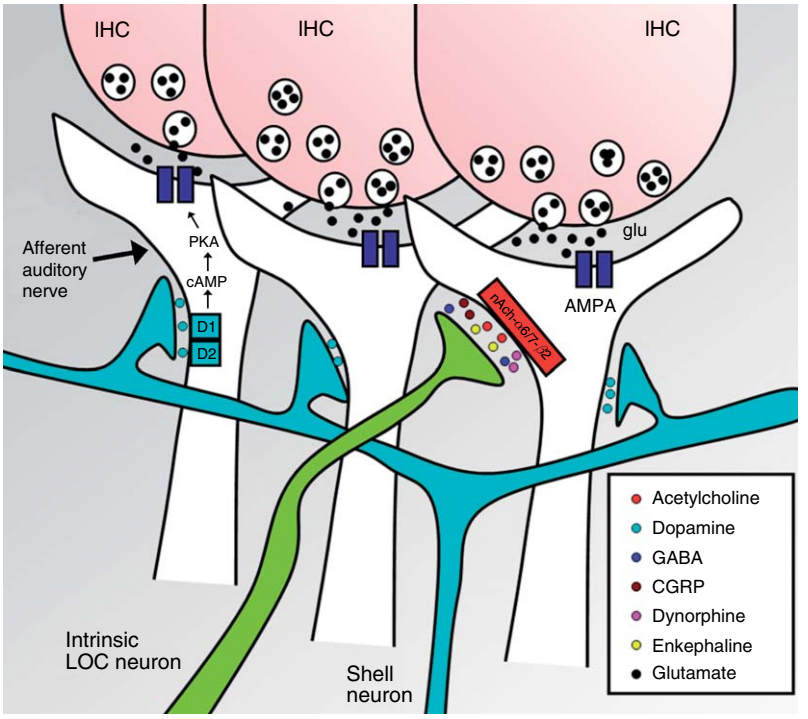

Figure 3 Lateral olivocochlear synapses with auditory-nerve fibers. Neurotransmitters released by lateral olivocochlear (LOC) fibers include: acetylcholine, dopamine, GABA, CGRP, dynorphines, and enkephalines. The main neurotransmitter between IHCs and auditory-nerve fibers is glutamate. In mice, LOC dopaminergic fibers originate from shell neurons (light blue) and are a separate group from LOC intrinsic fibers (green) that release acetylcholine and other neurotransmitters (Darrow, K. N. *et al.*, 2006a). The dopamine receptors in the auditory-nerve afferent fiber (D1/D2) through a G-protein regulate the intracellular concentration of cAMP and thus the activity of the protein kinase A (PKA), which phosphorilates AMPA glutamate-receptors (Niu, X. and Canlon, B. 2006). Acetylcholine released by LOC fibers is thought to activate receptors conformed by α6, α7, and β2 subunits (Morley, B. J. *et al.*, 1998). IHC, inner hair cell.

cochlea through the lateral efferent fibers. In agreement with previous observations (Safieddine, S. *et al.*, 1997), they also found that dopaminergic neurons are not equally distributed over the LSO. Most of them originate from the medial limb, the region of the LSO that receives high-frequency input. Consistently, they found dense tyrosine-hydroxylase labeling in the first and second cochlear turns and sparse or no labeling in the apical cochlear regions. These results are in contrast with evidence that shows no differences in the distribution of D1 receptors beneath IHCs along the guinea-pig cochlea (Niu, X. and Canlon, B., 2006) and a uniform dopaminergic innervation from base to apex in the mouse cochlea (Darrow, K. N. *et al.*, 2006a). It has been suggested that dopaminergic innervation may be important for high frequencies in the mammalian cochlea. This fact would explain the presence of dopaminergic fibers only in the basal turns of the cochlea in guinea-pig and through the whole cochlea in the mouse, which is a high-frequency mammal.

3.24.2.2 Cortico-Cochlear Pathways

Anatomic studies performed in a variety of animals have shown the existence of corticofugal pathways that originate in the auditory cortex and, after making synaptic contacts in various nuclei of the brainstem, reach the cochlea through the OC efferent fibers. This section presents a summary of the main findings on these cortico-cochlear pathways; for a more thorough review on the subject see Huffman R. F. and Henson O. W., Jr. (1990) and Winer J. A. (2005). A schematic view of the basic anatomy of the cortico-cochlear pathways is presented in Figure 4.

The largest descending pathway from the auditory cortex projects to the medial geniculate body, that is, the auditory thalamus. Each of the three main subdivisions of the medial geniculate body and the thalamic reticular nucleus receive projections from various auditory cortices (Winer, J. A. *et al.*, 2001). Tonotopic cortical areas project mainly to the tonotopic medial geniculate body and nontonotopic cortical areas

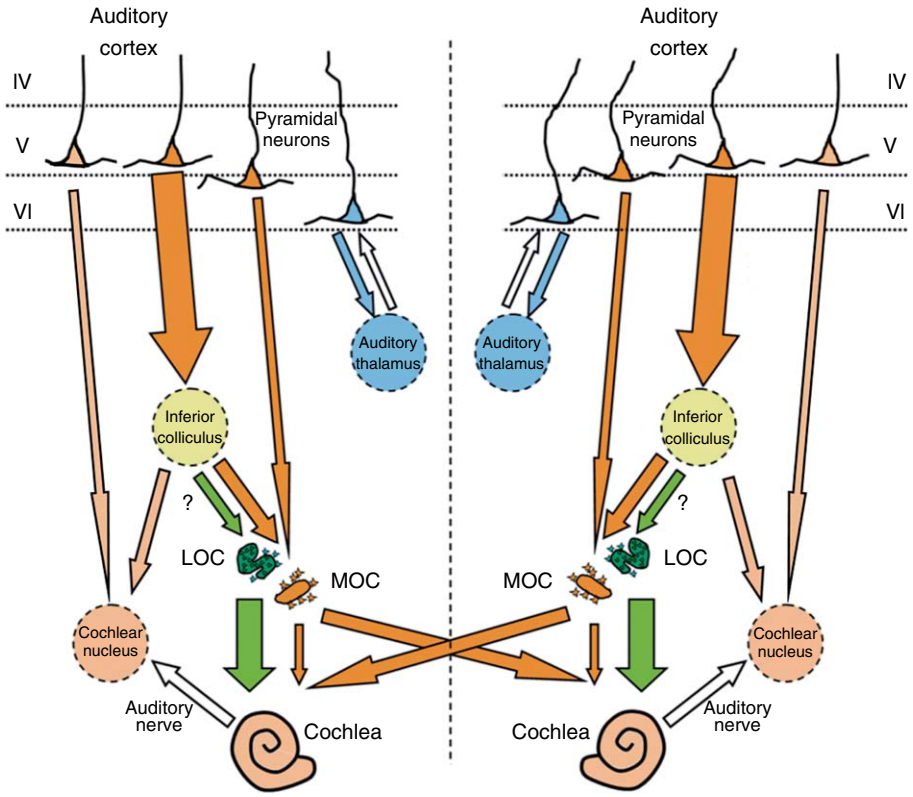

Figure 4 Diagram of cortico-cochlear pathways. Descending projections to the auditory thalamus emerge from pyramidal neurons located in layer VI of the auditory cortex (light blue arrows and cortical neurons). Corticofugal projections to the ipsilateral IC, superior olivary complex (orange arrows and cortical neurons), and to the cochlear nucleus (beige arrows and cortical neurons) emerge from different populations of pyramidal neurons located in layer V of the auditory cortex. There are also contralateral projections from the auditory cortex to the IC, superior olivary complex and cochlear nucleus (not shown in this schematic figure). Through the OC fibers (MOC and LOC fibers) the cortical pathways reach the contralateral and ipsilateral cochleae. Possible IC to LOC projection (green arrow with?; Groff, J. A. and Liberman, M. C. 2003).

project largely to nontonotopic thalamic regions. These projections emerge from pyramidal neurons located in the deepest part of layer V, and throughout layer VI of the auditory cortex (Winer, J. A. and Prieto, J. J., 2001). There is, however, no evidence of thalamic projections that reach the cochlea, and it seems that the projections from the auditory cortex to the medial geniculate body and to the reticular nucleus form a feedback loop with the ascending fibers to the auditory cortex.

For a long time the IC was seen as an obligatory synaptic station in the descending auditory pathways that reach the cochlear nucleus and the cochlea (Huffman, R. F. and Henson, O. W., Jr., 1990). The cortical fibers innervating the IC have their origin in pyramidal neurons located in layer V of the auditory cortex and project mainly to the dorsal and external cortices of the ipsilateral IC (Andersen, R. A. *et al.*, 1980; Faye-Lund, H., 1985; Herbert, H. *et al.*, 1991), although they also innervate other regions of the IC, including the central nucleus (Saldaña, E. *et al.*, 1996). There are multiple studies showing the presence of descending fibers that originate in the IC central nucleus and terminate in the dorsal cochlear nucleus and the superior olivary complex (Malmierca, M. S. *et al.*, 1996; Coomes, D. L. and Schofield, B. R., 2004a). Studies using double labeling have shown that descending collicular axons that innervate primarily the ipsilateral superior olivary complex make synaptic contacts mainly with MOC neurons (Thompson, A. M and Thompson, G. C., 1993; Vetter, D. E. *et al.*, 1993). Also, studies using multilabeling techniques in guinea-pigs have demonstrated the existence of cortico-colliculo-cochlear nucleus projections (Schofield, J. R. and Coomes, D. L., 2006).

In 1995, Feliciano and collaborators demonstrated in rats the presence of auditory-cortex projections that, bypassing the IC, reach directly the brainstem nuclei,

like lateral lemniscus, superior olivary complex, and cochlear nucleus (Feliciano, M. *et al.*, 1995). The existence of a direct cortico-cochlear nucleus pathway has also been confirmed in the guinea-pig (Schofield, J. R. and Coomes, D. L., 2006). Injections of a retrograde tracer in the cochlear nucleus and an anterograde tracer in the auditory cortex of the rat made it possible to show that the cochlear-nucleus cortical projections originate from large pyramidal neurons in layer V of the ipsilateral primary auditory cortex (Weedman, D. L. and Ryugo, D. K., 1996a) and that the pyramidal neurons make synapses exclusively with neurons located in the granule cell layer of the cochlear nucleus (Weedman, D. L. and Ryugo, D. K., 1996b).

Mulders W. H. and Robertson D. (2000a) combined auditory-cortex anterograde and cochlear retrograde tracing techniques to demonstrate in the rat that projections from pyramidal neurons located in layer V of the primary auditory cortex make synaptic contacts with MOC neurons that project to the cochlea. Afterward, using anterograde tracers, the presence of direct projections from the auditory cortex to the superior olivary complex was also demonstrated in the guinea-pig (Coomes, D. L. and Schofield, B. R., 2004b). The majority of the cortical axons terminate in the ipsilateral side where they innervate most of the superior olivary complex nuclei, with the largest number of fibers reaching the ventral nucleus of the trapezoid body and few fibers reaching the LSO. It has been established that the pyramidal neurons that project to the cochlear nucleus and to the superior olivary complex belong to different populations of neurons (Doucet, J. R. *et al.*, 2002). These anatomical results show that cortical neurons may exert a direct action on the activity of MOC neurons and consequently could modulate cochlear sensitivity (Mulders, W. H. and Robertson, D., 2000a).

3.24.3 Physiology of the Efferent System

From the early classical works on the physiology of the efferent system it is known that efferent OC neurons respond to sound at regular firing rates with frequency tuned responses (Brown, M. C., 1989) and that their activation produces an inhibitory effect in cochlear responses (Galambos, R., 1956; Fex, J., 1959; 1962).

Two main methods have been used to study the function of auditory efferents, activation and blocking of the efferent pathways. Activation has been performed by electrical stimulation at different levels of the efferent path and by contra- and ipsilateral acoustical stimulation. Blocking of the efferent function has been achieved by: surgical lesions, pharmacological neurotransmitter antagonists, and molecular deletion of relevant genes.

3.24.3.1 Electrical Stimulation of the Efferent System

To activate the efferent system, electrical stimulation with high-frequency current pulses has been applied at different levels of the efferent pathway: (1) at the midline of the floor of the fourth ventricle; (2) at the medial superior olive region; (3) at the round window; (4) at the IC; and (5) at the auditory cortex.

3.24.3.1.1 Effects on cochlear electrical responses and otoacoustic emissions

Most of the early information on the physiology of the efferent system was obtained by electrical activation of the MOC fibers with current pulses delivered at the point of fiber crossing in the midline of the floor of the fourth ventricle. The electrical stimulation of efferent fibers produced a reduction in the amplitude of the compound action potential (CAP) (Galambos, R., 1956), that is, the summated activity of the auditory nerve, and an increase in the amplitude of cochlear microphonics (CM) (Fex, J., 1959; 1962), that reflect a voltage drop produced by some weighted sum of currents generated in multiple hair cells. These CAP reductions and CM increases elicited by efferent stimulation disappeared after systemic injection of strychnine, a known blocker of efferent function (Figure 5; Desmedt, J. E. and Monaco, P., 1961). Efferent electrical stimulation was also shown to suppress the responses to tones recorded from single auditory-nerve fibers and intracellularly from IHCs, particularly at the characteristic frequency of the fiber or IHC (Guinan, J. J., Jr., 1996).

Soon after the discovery of otoacoustic emissions (OAEs) (Kemp, D. T., 1978), Mountain D. C. (1980) showed that electrical stimulation of MOC fibers reduces the amplitude of distortion product OAEs (DPOAEs) recorded in the ear canal. The fact that electrical activation of the MOC efferents can modify OAEs and IHC receptor potentials demonstrates that the efferent system through the activity of OHCs can regulate the tuning and sensitivity of cochlear mechanics and IHC responses (Dallos, P., 1992; Robles, L. and Ruggero, M. A., 2001).

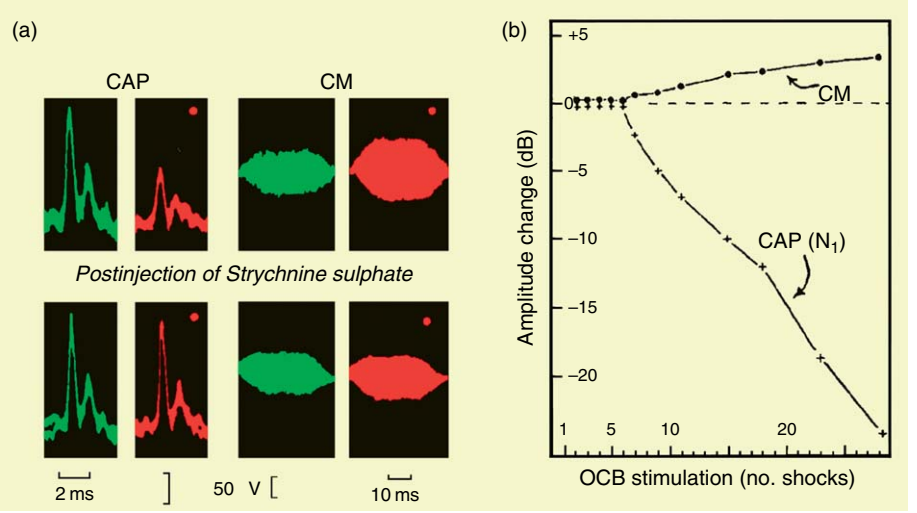

Figure 5 Effect of the electrical activation of MOC fibers on cochlear potentials. (a) Green traces show cochlear CAP and CM potentials in response to sound without efferent electrical stimulation. Red traces show same cochlear responses preceded by electrical activation of MOC fibers at the midline of the floor of the fourth ventricle. In the upper row a clear CAP reduction and CM increase is evident during electrical activation of MOC fibers. In the lower row this effect is blocked after an injection of strychnine. (b). Change of CAP and CM amplitudes as a function of the number of shocks at the fourth ventricle (OCB: olivocochlear bundle). Adapted from Desmedt, J. E. and Monaco, P. 1961. Mode of action of the efferent olivo-cochlear bundle on the inner ear. Nature 192, 1263–1265.

It has been shown in guinea-pigs that electrical stimulation at the round window produces similar reductions in CAP amplitude that the activation of efferent fibers at the floor of the fourth ventricle, and consequently this less invasive technique has been proposed as an alternative method of activation of efferent fibers innervating the cochlea (Rajan, R. and Johnstone, B. M., 1983).

A comparison of the effects of selective electrical stimulation of MOC efferents by an electrode placed near MOC cell bodies and of stimulation of efferent fibers at the floor of the fourth ventricle was performed by Gifford M. L. and Guinan J. J., Jr. (1987) to differentiate the effects produced by medial and lateral OC efferent fibers. The results showed qualitatively similar reductions in CAP and increases in CM amplitudes produced by electrical activation of the MOC neurons and the fourth-ventricle fibers. However, a quantitative analysis showed that the reduction in CAP amplitude produced by fourth-ventricle stimulation amounted to about the sum of the CAP amplitude reductions produced by selective electrical stimulation of one-side MOC neurons in the contra and ipsilateral ears. Consequently, the authors postulated that in their experiments, as well as in previous ones, the efferent effects elicited with fourth-ventricle OC stimulation, due to the proximity of the uncrossed fibers to the stimulation place, most probably corresponded to the joint effect of crossed and uncrossed medial OC fibers. Some studies have reported that the electrical stimulation of MOC fibers, concomitant to the changes in CAP amplitude, produces increases in CAP (N1) latency (Dayal, V. S., 1968; Gifford, M. L. and Guinan, J. J., Jr., 1987), but other studies have failed to observe them (Desmedt, J. E. *et al.*, 1971; Rajan, R. and Johnstone, B. M., 1983).

In auditory-nerve fibers, electrical stimulation of MOC neurons (and at the fourth ventricle) produces a decrease in spontaneous rate, which is stronger for the lower spontaneous rate fibers, and shifts the fiber firing rate–sound level functions to higher sound levels, decreasing their spike rate at the plateau. MOC activation also raises the thresholds for tones at the characteristic frequency and decreases the sharpness of the nerve-fiber tuning curves. High-spontaneous-rate fibers have smaller increases in threshold, and low-spontaneous-rate fibers larger increases (Guinan, J. J., Jr. and Gifford, M. L., 1988; Guinan, J. J., Jr.,1996). Figure 6 illustrates some of the efferent effects on auditory-nerve responses discussed in this section.

3.24.3.1.1.(i) Mechanisms of inhibition of OHC activity Electrical stimulation of efferent fibers in the turtle isolated cochlea was shown to produce slow hyperpolarizing postsynaptic potentials in hair cells (Art, J. J. *et al.*, 1982). Later experiments in guinea-pig

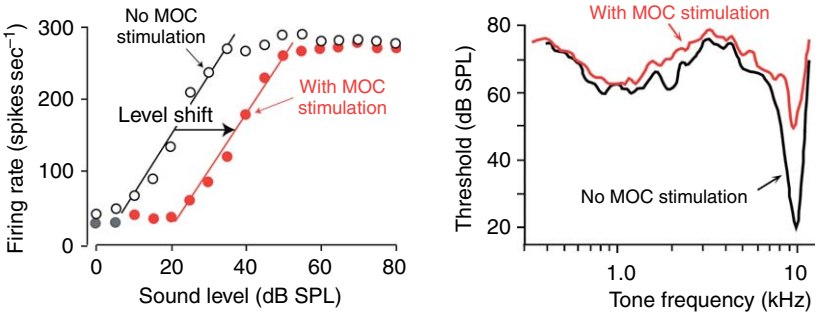

Figure 6 Examples of MOC effects on the activity of auditory nerve fibers. Left panel shows auditory-nerve firing rate versus sound-pressure level with and without MOC stimulation. Data are from a high-spontaneous fiber recorded from a cat. MOC activity produces a shift of the nerve-fiber firing-rate curve to higher sound-pressure levels. Right panel: Tuning curves with and without MOC stimulation. MOC stimulation increases the response thresholds at frequencies around the characteristic frequency of the auditory-nerve fiber. Adapted from Guinan, J. J., Jr. 2006. Olivocochlear efferents: Anatomy, physiology, function, and the measurement of efferent effects in humans. Ear Hear. 27: 589–607.

isolated OHCs demonstrated that ACh applied to their basal pole binds to the ACh nicotinic receptor inducing a Ca^{2+} influx current. The increase in intracellular Ca^{2+} activates Ca^{2+}-dependent K^+ channels producing an increase in cell input conductance and an outward K^+ current that hyperpolarizes the OHC (Housley, G. D. and Ashmore, J. F., 1991; Erostegui, C. *et al.*, 1994; Evans, M. G., 1996) (Figure 2). This unusual fast inhibitory synapse, which through nicotinic ACh receptors activates low-conductance Ca^{2+}-dependent SK2 channels, has short rise and decay time constants of 6 and 30 ms, respectively, mainly determined by the Ca^{2+} gating of the K^+ currents (Oliver, D. *et al.*, 2000). A Ca^{2+}-dependent potassium channel has been reconstituted within a heterologous system by co-expressing a low-conductance potassium channel cloned from the mouse cochlea with the $\alpha 9/\alpha 10$-nicotinic acetylcholine receptor, showing that these two elements are sufficient to reconstitute the efferent synaptic response (Nie, L. *et al.*, 2004).

It has been shown that OHCs have a membrane potential-dependent motor capability by which they elongate and contract under hyperpolarization and depolarization, respectively (Brownell, W. E. *et al.*, 1985; Ashmore, J. F., 1987). This electromotile effect, driven by voltage-dependent conformational changes of a transmembrane protein, prestin (Zheng, X. Y. *et al.*, 2000), performs as a cochlear amplifier by boosting cochlear vibrations at each cochlear location for stimuli at frequencies close to its characteristic frequency. Both of the effects of ACh on OHCs, described above, which induce changes in their electrical responses affect cochlear amplification, since hyperpolarization of OHCs would elongate them and the increase in input conductance would reduce sound-induced receptor potentials modifying the OHC electromotile response. However, ACh has been found to also produce increases in OHC axial compliance and electromotile response that occur with a significantly greater latency than the effects on OHC electrical responses and that are simultaneous with Ca^{2+} release from intracellular stores (Dallos, P. *et al.*, 1997). The ACh-induced increase in OHC electromotile response is probably accounted by the increase in axial compliance and may be related to slow effects produced by OC activation (see following section). Surprisingly, this increase in electromotility induced by ACh in isolated OHCs is opposite to the *in vivo* effects of efferent-system activation and cochlear ACh perfusion that reduce cochlear amplification; it is not clear how these different results can be reconciled.

3.24.3.1.1.(ii) Fast and slow effects of olivocochlear activation Sridhar T. S. *et al.* (1995) described new slow effects on cochlear responses produced by electrical activation of OC fibers, which occur with time constants of 25–50 s, three orders of magnitude slower than the previously reported efferent cochlear effects. These slow effects are similar to the fast effects in that they include a reduction in eight-nerve CAP concomitant to an increase of CM during electrical activation of the MOC bundle (Figure 7). The new slow effects are also similar to the classical fast effects in that they are blocked by similar concentrations of various cholinergic antagonists, suggesting that both effects are mediated by the same cellular receptor. However, one important

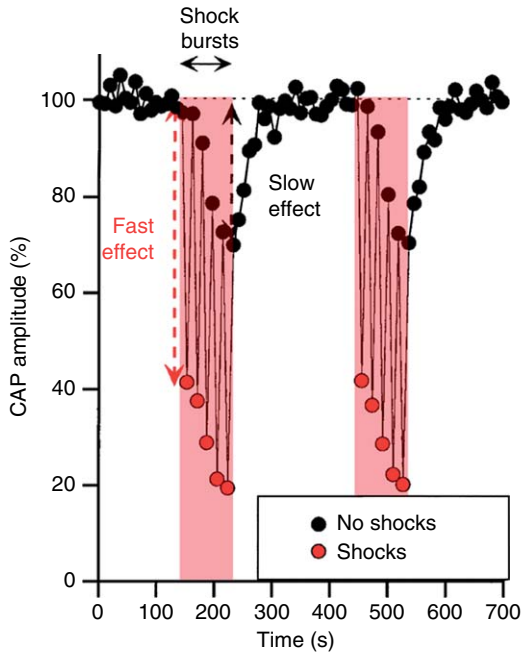

Figure 7 Fast and slow OC effects on CAP amplitude. The fast effect (red arrow) is a reduction in magnitude of CAP responses to tones with shocks (red circles) compared with the CAP magnitudes without shocks (black circles). The slow effect is measured as the cumulative decrease in the amplitude of CAP with repeated shock bursts (black arrow). Adapted from Sridhar, T. S., Brown, M. C., and Sewell, W. F. 1997. Unique postsynaptic signaling at the hair cell efferent synapse permits calcium to evoke changes on two time scales. J. Neurosci. 17, 428–437.

difference between the fast and slow effects in guinea-pig, besides their time courses, is that the former has a peak effect for frequencies between 6 and 10 kHz and the latter for frequencies between 12 and 16 kHz.

Perfusion of the cochlea with ryanodine, an agonist of calcium-induced calcium release from endoplasmic reticulum, enhanced the fast and slow effects on CAP and CM, probably by increasing calcium concentration at the cell membrane and thus increasing the conductance of OHCs. On the other hand, cochlear perfusion with an antagonist of reticulum calcium ATPase (SERCA) enhanced selectively the slow effects, suggesting that these effects are dependent on calcium stored in a compartment other than the OHC synaptic region (Sridhar, T. S. *et al.*, 1997). Expression of type-I ryanodine receptors has been demonstrated in OHCs of the apical turn of the rat cochlea and consistently, whole-cell voltage-clamp recordings made in OHCs from that location have shown that ryanodine modulates the potassium current evoked by acethylcholine (Lioudyno, M. I. *et al.*, 2004). These results suggest that, as in muscle sarcoplasmic reticulum, the cistern (synaptoplasmic cistern) in OHCs could act to assure a fast activation of the Ca^{2+}-dependent K^{+} current that turns the nicotinic receptor excitation into synaptic inhibition.

3.24.3.1.2 Medial olivocochlear effects on cochlear mechanics

Mountain D. C. (1980), and later Siegel J. H. and Kim D. O. (1982), showed that the electrical activation of OC fibers at the fourth ventricle can modulate the amplitude of distortion-product OAEs, an effect that reflects changes in cochlear mechanics. Afterward, direct mechanical measurements demonstrated that electrical activation of MOC fibers produces a characteristic-frequency-specific loss of sensitivity in basilar membrane vibrations (Murugasu, E. and Russell, I. J., 1996a; Dolan, D. F. *et al.*, 1997). For tones near the characteristic frequency, efferent stimulation linearizes the compressive basilar membrane displacement–intensity functions and shifts the steep segment of the curves to higher intensities, by up to 30 dB. All of these efferent effects were blocked by strychnine, a known blocker of efferent function. Consistent with the electrically produced efferent effects, cochlear perfusion with acetylcholine produced transient losses of sensitivity and linearization of the compressive displacement–intensity functions of tone-evoked basilar membrane responses (Murugasu, E. and Russell, I. J., 1996b). In addition, electrical efferent stimulation has been reported to enhance basilar membrane responses at frequencies well above the characteristic frequency and at high intensities (Dolan, D. F. *et al.*, 1997); however, a comparable effect has not been observed previously in auditory nerve responses.

Sound-evoked cochlear vibrations were also shown to be modulated over two different time scales by electrical activation of MOC fibers (Cooper, N. P. and Guinan, J. J., Jr., 2003). As previously demonstrated in cochlear potentials (see Section 3.24.3.1.1.(ii)), both fast (10–100 ms) and slow (10–100 s) efferent effects decreased cochlear mechanical responses for low and moderate intensity tones at frequencies close to the characteristic frequency. The fast inhibition of basilar membrane motion was accompanied by phase leads, while the slow inhibition was accompanied by phase lags, suggesting that two different mechanical processes underlie these two effects. (For further information, see Cooper, N. P. and Guinan, J. J., Jr., 2006.)

3.24.3.1.3 Efferent modulation by electrical activation of the inferior colliculus

Electrical stimulation of the central nucleus and external cortex of the IC produced large reductions in DPOAE magnitudes (up to 25 dB), while stimulation of the dorsal cortex produced little or no change in DPOAEs (Scates, K. W. *et al.*, 1999). However, since much smaller DPOAE reductions were observed in paralyzed animals (Mulders, W. H. and Robertson, D., 2000b) than those previously obtained in unparalyzed animals, it is likely that the observed large effects could partly be due to middle-ear muscle contractions. The stronger effects obtained with the stimulating electrodes positioned in the central nucleus and external cortex, compared with those obtained with the electrodes in the dorsal cortex, are consistent with previous anatomical evidence showing that the former regions have numerous and the latter region only sparse projections to the ipsilateral superior olivary complex (see Section 3.24.2.2).

Electrical activation of the central nucleus and external cortex of the IC also produces reductions in CAP amplitude and increases in CM potentials that are similar, although smaller than those obtained by direct electrical stimulation of MOC fibers at the fourth ventricle (Mulders, W. H. and Robertson, D., 2000b). Using the same microelectrodes to electrically stimulate and to record from neurons from different IC sites it was shown that, in the central nucleus, the characteristic frequency of the sharply tuned recorded units closely matches the stimulus frequency at which the maximum CAP reduction was observed. In contrast, neurons from the external cortex presented broad tuning and their stimulation had a weak and broadly tuned effect in CAP amplitudes. The stimulation of the IC dorsal cortex had no effect on cochlear responses (Ota, Y. *et al.*, 2004).

Surprisingly, in addition to these efferent effects, electrical stimulation at other IC sites elicited bilaterally CAP amplitude enhancements or reductions that could last for periods of 3–20 min after shock termination. These novel long-lasting efferent effects were attributed to activation of LOC fibers that enhance or reduce auditory-nerve activity (CAP and eighth-nerve ensemble background activity; see Section 3.24.3.4.2.(i)) without affecting measures of OHC function (cochlear microphonics and DPOAEs). They differed from the efferent effects elicited by MOC activation, in that their magnitudes were independent of the frequency and intensity of acoustic stimuli (Groff, J. A and Liberman, M. C., 2003).

Consistent with the previous observations, it has been shown that the IC can produce diverse effects on the activity of auditory-nerve single fibers. In a recent study, electrical activation of the IC produced inhibitory effects, with a loss in response sensitivity to tones in 53% of the recorded fibers and excitatory effects, with an increase in response sensitivity in 5% of the fibers (Mulders, W. H. and Robertson, D., 2005). The activation of the LOC system, in addition to the MOC system, could explain the diversity of effects produced by the IC at the level of single auditory nerve fibers.

3.24.3.1.4 Efferent modulation by electrical activation of the auditory cortex

There are several lines of physiological evidence indicating that corticofugal projections from the auditory cortex modulate the responses of subcortical nuclei. Moreover, a few studies show that the auditory cortex can modulate auditory responses even at a cochlear level.

Electrical activation of the ipsilateral and contralateral auditory cortices modulates the spontaneous and sound-evoked activity of units recorded in the central nucleus of the IC in guinea-pigs. The contralateral cortex is more effective in eliciting inhibitory effects in IC units, while the ipsilateral cortex is more effective in producing excitatory effects on spontaneous activity of the units (Torterolo, P. *et al.*, 1998). Electrical stimulation of the auditory cortex also modulates the response properties of units recorded intracellularly from the medial geniculate body, producing excitatory as well as inhibitory modulations (Xiong, Y. *et al.*, 2004).

It has been shown in the mustached bat that focal electrical stimulation (or pharmacological inactivation) of the constant-frequency Doppler-shift area of the auditory cortex can modulate in a highly specific way the amplitude and tuning of cochlear microphonics. This effect, although bilaterally present, is stronger at the contralateral auditory cortex (Xiao, Z. and Suga, N., 2002a; 2002b).

Corticofugal modulations of cochlear responses have also been studied in humans, in a group of patients with refractory epilepsy during their presurgical chronic intracerebral electroencephalography. In these patients, during this protocol, in which the auditory cortex and other nonauditory cortices are electrically stimulated to delimit epileptogenic areas in the brain, evoked OAEs were simultaneously recorded, as a measure of cochlear function. Electrical stimulation of the contralateral auditory cortex

produced a significant reduction of evoked OAEs in all the patients, while there was no change under stimulation of nonauditory cortical areas (Perrot, X. *et al.*, 2006). These results imply that, in humans, as in bats, the anatomical pathways from the auditory cortex to the cochlea are functional, providing a top-down control on incoming auditory information.

3.24.3.2 Acoustic Activation of the Efferent System

Since it was known that acoustical stimulation activates the medial OC neurons (Fex, J., 1962) and that these neurons can modify cochlear responses (Galambos, R., 1956), it was natural to look for acoustically evoked efferent effects in cochlear responses. Acoustic stimulation is certainly a more physiological method to activate the OC system than electric stimulation, and since it is noninvasive, it has been used to asses the auditory efferent function in awake animals and in humans. Figure 8 displays a schematic diagram explaining the experimental setting for the acoustic activation experiments.

3.24.3.2.1 Acoustic efferent effects in experimental animals

Buño W. (1978) showed in anesthetized animals that contralateral acoustic stimulation at low intensities modifies the tone-evoked responses of single auditory-nerve fibers in the ipsilateral ear. The suppression effect is maximal for low- and medium-spontaneous-rate fibers with characteristic frequencies below 3 kHz and is highly dependent on the intensity and frequency of the tones, being strongest for ipsi- and contralateral

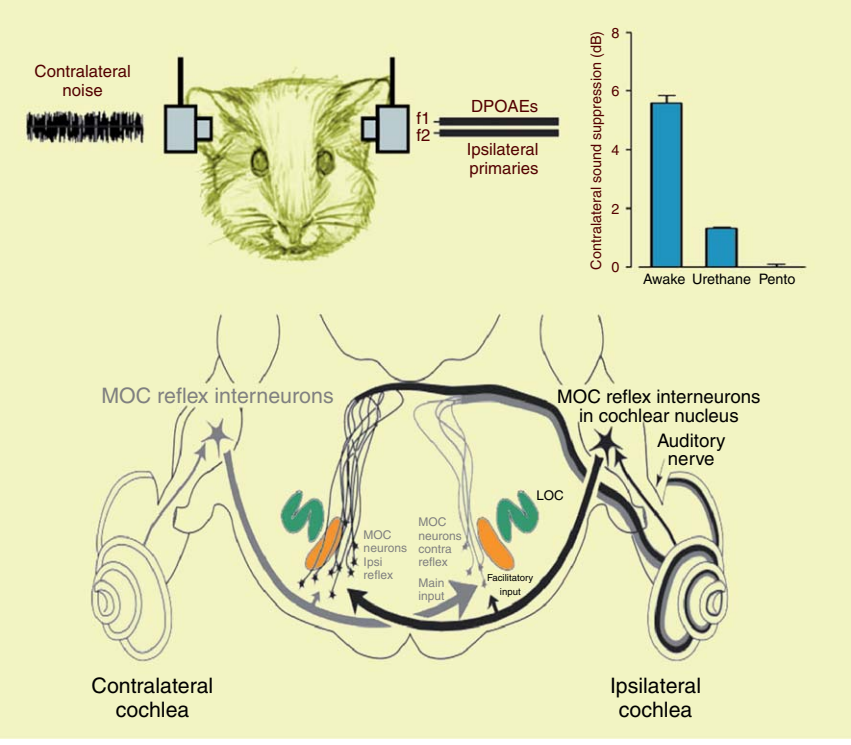

Figure 8 Acoustic activation of the efferent system. Top: Illustration of the method used to measure the acoustic efferent effect. The amplitude of ipsilateral DPOAEs is measured in the presence of contralateral noise. Bottom: Anatomy of the acoustic efferent effect. The anatomic pathway of the ipsilateral acoustic efferent reflex has double crossing fibers: (1) from the ipsilateral cochlea, through the cochlear nucleus, to the contralateral MOC neurons and (2) from contralateral MOC neurons to the ipsilateral cochlea. In contrast the contralateral reflex has only one crossing (light gray arrow pathway in the illustration) of afferent fibers from the contralateral cochlear nucleus to the subset of MOC uncrossed neurons that project to the ipsilateral cochlea (see de De Venecia, R. K. *et al.*, 2005). Top right: Effective attenuation of the efferent effect measured in awake and urethane- and pentobarbitone-anesthetized guinea-pigs. Adapted from De Venecia, R. K., Liberman, M. C., Guinan, J. J. Jr., Brown, M. C. 2005. Medial olivocochlear reflex interneurons are located in the posteroventral cochlear nucleus: a kainic acid lesion study in guinea-pigs. J. Comp. Neurol. 487, 345–360 and Guitton, M. J., Avan, P., Puel, J. L., and Bonfils, P. 2004. Medial olivocochlear efferent activity in awake guinea-pigs. Neuroreport. 15, 1379–1382.

tones with frequencies close to the nerve-fiber characteristic frequency. This contralateral-sound suppression has a much slower time course than two-tone suppression, with onset and offset times of more than 100 ms. The fact that the suppressive effect is eliminated by a complete section of the OC bundle within the internal auditory meatus, but remains after section of the crossed OC fibers at the floor of the fourth ventricle implies that it is mediated by uncrossed MOC fibers (Warren, E. H., 3rd and Liberman, M. C., 1989). There is evidence showing that ipsilateral noise also suppresses ipsilateral tone-evoked responses through MOC efferents.

Two MOC reflex circuits have been described for each cochlea, one that is activated by contralateral and another by ipsilateral acoustic stimulation (Figure 8). The ipsilateral MOC reflex circuit crosses twice the midline of the brainstem, comprising: afferent auditory-nerve fibers that reach the ipsilateral posteroventral cochlear nucleus (PVCN), interneurons from the PVCN whose axons cross the midline to make synaptic contact at the opposite side with efferent MOC neurons, that project back across the midline to the OHCs of the ipsilateral cochlea. In contrast, the contralateral MOC reflex has only one midline crossing, the contralateral afferent auditory-nerve fibers make synaptic contact with interneurons from the contralateral PVCN, which cross the midline to contact ipsilateral MOC neurons that project through uncrossed fibers to the OHCs of the ipsilateral cochlea (De Venecia, R. K. *et al.*, 2005). This means that contralateral noise efferent suppression is mediated by uncrossed MOC fibers, while ipsilateral efferent suppression is mediated by crossed MOC fibers.

In awake guinea-pigs, noise in the contralateral ear reduces the power of eighth-nerve ensemble background activity recorded from the ipsilateral round window, revealing a decrease in auditory-nerve spontaneous activity (Lima da Costa, D. *et al.*, 1997a; Dolan, D. F. *et al.*, 1990). Contralateral tones or noise also decrease(s) the amplitude of the ipsilateral auditory-nerve CAP, with a frequency and level dependency similar to that of tone-evoked responses from auditory-nerve fibers. In spite of the constancy of auditory-nerve-fiber thresholds between animals, the magnitudes of efferent CAP reductions display significant interanimal variability, attributed mainly to variability in the level of activity of OC efferent neurons. Consequently, the measurement of CAP suppression by contralateral sound has been proposed as a rapid assessment of the strength of the OC reflex, which depends on the activity level of efferent MOC neurons (Liberman, M. C., 1989).

The magnitude of the DPOAEs recorded in the ipsilateral ear is also reduced by the presence of a simultaneous noise in the contralateral ear. This suppression is completely abolished by a midline sagittal section of the brainstem, demonstrating that it is an effect mediated by the MOC fibers (Puel, J. L. and Rebillard, G., 1990). It is, however, difficult to compare the strengths of the efferent effect assessed by measuring the changes in magnitude of auditory-nerve CAP and those of DPOAEs. The former measure reflects the summed activity of the whole auditory nerve, which could also be affected by LOC effects, while the latter reflects a mechanical nonlinear response whose magnitude is not clearly related to the amplitude of the traveling wave at the primary sites. A direct comparison in anesthetized cats of the magnitudes of contralateral-noise suppression obtained with the two measures showed that the effective suppression measured with CAP is generally larger than that measured with DPOAEs, with differences reaching as much as 10 dB (Puria, S. *et al.*, 1996).

Interestingly, measuring DPOAEs it has been found that the activation of the efferent system can not only produce reductions in the amplitude of OAEs, but also enhancements. The first to report this kind of enhancements were Siegel J. H. and Kim D. O. (1982), who used electrical activation of the OC fibers at the floor of the fourth ventricle in chinchilla. More recently, it has been reported that efferent activation can elicit decreases and also enhancements in DPOAEs, and that the change from one effect to the other is level dependent. A change in just 1 dB in sound-pressure level in one of the stimulus primary tones can produce a transition in the effect, from decrease to enhancement of the DPOAEs (Maison, S. F. and Liberman, M. C., 2000). This phenomenon, named the bipolar effect, has also been observed in DPOAEs measured in humans during contralateral acoustic stimulation (Muller, J. *et al.*, 2005).

A pharmacological study of the acoustic efferent effect found that cochlear perfusions of nanomolar concentrations of bungarotoxin (a nicotine antagonist) and of strychnine (a glycine antagonist that also blocks nicotinic receptors) blocked the suppression of DPOAEs produced by contralateral-noise activation of MOC neurons, indicating that the suppression was mediated by a nicotinic receptor (Kujawa, S. G. *et al.*, 1994). Enhancements of neural potentials and DPOAEs have recently been reported during recovery from acoustic activation of auditory efferents (Maison, S. F. *et al.*, 2007a). In contrast to the classical suppressive efferent effect, the enhancement effect is not blocked by strychnine and is present in mice with deletion of

the $\alpha 9$ cholinergic receptor (see Section 3.24.3.3.2), implying that this enhancement effect is not dependent on cholinergic neurotransmission.

Most of the effects of MOC fibers in cochlear responses had been previously studied in anesthetized animals, and since there was evidence showing that the activity of medial OC neurons was dependent on the level of anesthesia it became important to make the measurements in awake animals. A comparison of contralateral-sound suppression in awake and anesthetized guinea-pigs found that the efferent suppression is much weaker in the urethane-anesthetized than in the awake animal, and that it is even weaker in the pentobarbitone-anesthetized animal (Figure 8; Guitton, M. J. *et al.*, 2004; Boyev, K. P. *et al.*, 2002). These results suggested that suppression measurements performed in anesthetized animals probably underestimate the magnitude of the physiological efferent effects.

3.24.3.2.2 Acoustic efferent effects measured in humans

As stated by Puria S. *et al.* (1996), it is difficult to compare the strength of the OC reflex reported in humans, usually assessed by measuring OAE magnitude changes, with that reported in experimental animals, appraised by the changes in auditory-nerve CAP magnitude. Most of the studies on acoustic stimulation of the efferent pathway performed in humans have measured the effect on OAEs, because it involves a relatively easy and noninvasive measurement. Only exceptionally the acoustic efferent effect has been assessed by measuring auditory-nerve CAPs, recorded at the external ear canal or at the eighth nerve in patients undergoing surgery.

Folsom R. C. and Owsley R. M. (1987) recording click-evoked CAPs from the external ear canals of normal subjects found a reduction in the amplitude of N1 during the presentation of contralateral tones, with no change in N1 latency. Later studies found that contralateral acoustic stimulation, at sound levels below the stapedial-reflex threshold, could modulate different types of OAEs recorded in the ipsilateral ear of human subjects. Contralateral tones at frequencies within an octave of the frequency of an ipsilateral spontaneous OAE changed the frequency and amplitude of the emission (Mott, J. B. *et al.*, 1989). Also, broadband noise stimulation of the contralateral ear in humans produced a reduction in the amplitude of transiently evoked OAEs (TEOAEs) (Collet, L. *et al.*, 1990) and also in DPOAEs (Moulin, A. *et al.*, 1993). The facts that, in both of these studies, suppressions were not found in unilateral deaf subjects discarded that the observed effects could be produced by acoustic bone transmission.

The effect of contralateral noise on CAP responses was subsequently studied by recording directly from the auditory nerve during retrosigmoid surgery in humans (Chabert, R. *et al.*, 2002). Using this method, which produces more stable results than the recordings from the ear canal, the effective attenuation of contralateral noise on CAP amplitudes reached up to 10 dB. The study concluded that, as in the case of experimental animals, contralateral-sound suppression measured at the neural level is considerably higher than that measured with OAEs (about 10 dB vs. 1–4 dB).

Interestingly, the medial OC system strength, measured as equivalent attenuation of the click-evoked OAEs during contralateral-noise stimulation is stronger in the right than left ear in right-handers (Khalfa, S and Collet, L., 1996), while being symmetrical in left-handers (Khalfa, S. *et al.*, 1998). It is known that TEOAEs are larger in the right than in the left ear (Khalfa, S. *et al.*, 1997; Sininger, Y. S. and Conne-Wesson, B., 2004), but this cochlear asymmetry is independent of the greater attenuation effect in the right than left ear, which is mediated by MOC efferents (Khalfa, S. *et al.*, 1998). Also, contralateral acoustic suppression is stronger in professional musicians than in nonmusicians, with a similar left/right asymmetry in both groups (Perrot, X. *et al.*, 1999).

3.24.3.3 Lesion Studies of the Efferent System

Lesion studies to evaluate the efferent function in most cases have disrupted the efferent pathway at one of three locations: (1) the midline of the floor of the fourth ventricle, severing the crossed OC fibers; (2) the vestibular nerve or at the vestibulo-cochlear anastomosis, disrupting all efferent fibers that innervate one cochlea; or (3) at the level of the auditory cortex, eliminating the central control to the periphery (the first is performed in animals and the last two in animals and humans).

3.24.3.3.1 Section of olivocochlear efferents in animals

Acute sections of the OC fibers at the midline of the fourth-ventricle floor have often been used to eliminate the electrical or acoustic efferent effects measured in cochlear responses, to confirm the efferent involvement in the observed effects. In this section only the

physiological and behavioral consequences of chronic cochlear de-efferentation are presented.

3.24.3.3.1.(i) Physiological consequences of olivocochlear sections Several studies have shown evidence, although not always consistent, of the presence of tonic activity in the efferent system. A section of the OC bundle at the midline of the fourth ventricle in the guinea-pig produced a reduction of about 5% in CM amplitude, whereas a complete section of the OC fibers to the cochlea produced a reduction near 14% (Rossi, G. *et al.*, 1964). Later studies in the same species also found reductions in CM amplitude for lateral sectioning of the brainstem (which probably sections both the crossed and uncrossed medial fibers), but not for midline sections at the fourth ventricle, which sections only the crossed fibers (Bonfils, P. *et al.*, 1987). Sectioning of both, the medial and lateral OC fibers in chinchillas produced increases in DPOAEs of 5–20 dB, at high intensity levels and frequencies between 1 and 2 kHz, but no changes at frequencies of 4 and 8 kHz. In contrast, de-efferented chinchillas presented reductions in CM amplitude at all frequencies tested (1–8 kHz) and at all intensities (Zheng, X. Y. *et al.*, 2000).

Chronic de-efferentation in adult cats did not change thresholds, tuning curves and firing rate–level functions of single auditory-nerve fibers, but produced significant decreases in spontaneous rates (Liberman, M. C., 1990). However, chronic de-efferentation in neonatal cats after a year produced threshold increases and decreases in sharpness of tuning of auditory-nerve fiber responses, suggesting that OC efferent innervation may be critical for the proper development of the active mechanical processes (Walsh, E. J. *et al.*, 1998). Chronic de-efferentation in chinchillas produced a significant decrease in the spontaneous discharge rate of auditory nerve fibers (Zheng, X. Y. *et al,* 1999), consistent with previous observations in cats. However, de-efferentation in chinchillas also produced changes in neural responses not observed previously in cats, as decreases in the dynamic range of discharge rate–level functions and hypersensitive tails in the tuning curves of auditory-nerve fibers with characteristic frequencies between 2 and 8 kHz.

3.24.3.3.1.(ii) Behavioral consequences of olivocochlear sections The behavioral consequences of chronic sections of the OC fibers in quiet conditions are controversial. On the other hand, most studies that have assessed the effects of chronic sections in background noise have found some impairment after severing the efferent pathway.

In cats, the section of the crossed efferent fibers at the midline of the fourth-ventricle floor did not affect pure tone detection thresholds in quiet between 250 Hz and 14 kHz (Trahiotis, C. and Elliott, D. N., 1970; Igarashi, M. *et al.*, 1972), neither did it affect frequency discrimination thresholds for stimuli at 8 kHz or intensity discrimination thresholds at 10 kHz (Igarashi, M. *et al,* 1979a; 1979b). However, in monkeys it was found that transection of the crossed OC fibers produced increases in frequency discrimination thresholds, for tones at 1 and 4 kHz presented in quiet conditions (Capps, M. J. and Ades, H. W., 1968).

May B. J. and McQuone S. J. (1995) trained cats in an intensity discrimination task in quiet and in the presence of noise, and performed bilateral lesions of the OC efferent fibers at the fourth-ventricle floor. Olivocochlear lesions were confirmed by AChE staining of efferent projections to the cochlea and by measuring the contralateral-noise CAP suppression. They found that intensity discrimination of tones at 8 kHz was affected by the lesions only when tested in the presence of noise, but not in quiet. Similarly, in cats trained in a sound localization task, bilateral lesions of OC efferents at the brainstem produced a significant deficit in localization only when tested in noise, but not in quiet (May, B. J. *et al.*, 2004). However, this initial deficit in sound localization observed in the presence of noise disappeared after five to six sessions of testing, suggesting that compensatory behaviors minimize the functional deficits along weeks, and that probably in humans these compensatory behaviors are also present.

In monkeys trained to discriminate human speech sounds in noise, a lesion in the midline of the fourth ventricle significantly impaired their performance in the behavioral task (Dewson, J. H., 3rd, 1968). Likewise, bilateral lesions of the OC system in cats produced significant impairment in the discrimination of vowel formants in the presence of noise, especially for high-intensity-noise backgrounds (Hienz, R. D. *et al.*, 1998).

3.24.3.3.2 Vestibular-nerve section in humans

Since OC fibers reach the cochlea through the vestibular nerve, patients whose vestibular nerve has been severed due to pharmacological untreatable vertigo constitute a human model of auditory de-efferentation. Several psychoacoustic tasks indicate that sound

detection, intensity discrimination, frequency selectivity, and loudness adaptation are not affected after vestibular neurotomy (Scharf, B. *et al.*, 1994; 1997). The only clear difference in these patients is that most of them detect unexpected frequencies in noise better than before surgery, suggesting that the efferent system is involved in the filtering of frequencies during attention (see Section 3.24.4.4.2).

In a study performed in a group of patients who had undergone vestibular neurotomy, the suppression produced by contralateral broad band noise on click-evoked OAEs was greatly reduced in comparison with normal subjects. In another group of patients with facial nerve paralyses (Bell's palsy), that abolishes the stapedial reflex, no difference was found in the magnitude of contralateral suppression by noise with that measured in control ears (Giraud, A. L. *et al.*, 1995). Although these results are evidence that the MOC efferent system is involved in the suppression by contralateral acoustic stimulation, the existence of residual contralateral-sound suppression in supposedly de-efferented patients suggests that maybe in humans not all efferent fibers travel along the vestibular nerve (Labrousse, M. *et al.*, 2005).

Amplitude suppression produced by contralateral sound in click-evoked OAEs is accompanied in normal subjects by a phase advance, which was reduced in de-efferented (vestibulotomized) patients (Giraud, A. L. *et al.*, 1996). Similarly, contralateral sound reduces DPOAE latencies for low-frequency primary tones at levels below 60 dB SPL, except in vestibular neurotomized patients who, in identical experimental conditions, showed increased latencies, suggesting the involvement of two different mechanisms in the modulation of DPOAEs latencies (Giraud, A. L. *et al.*, 1997a).

3.24.3.3.3 Ablation of the auditory cortex

Bilateral removal of the insular–temporal cortex in cats, changes the temporal properties of evoked potentials to paired clicks at the cochlear nucleus, suggesting a corticofugal regulation of afferent responses in the first synapses of the auditory pathway (Dewson, J. H. *et al.*, 1966). Khalfa S. D. *et al.* (2001a) studied humans in whom the temporal superior gyrus (auditory cortex location) was surgically removed due to epilepsy refractory to pharmacological treatment. After the cortical resection the patients showed a reduction in MOC function, assessed by TEOAEs and contralateral broadband noise, in both cochleae, but especially in that contralateral to the cortical ablation. These results imply that the auditory-cortex activity modulates the MOC efferent reflex in humans.

3.24.3.4 Manipulating Efferent Neurotransmission

This section presents experimental results obtained by different means of modifying efferent neurotransmission. It first describes the consequences of molecular deletion of target genes (*α9-nicotinic acetylcholine, αCGRP, $GABA_A$*) relevant for the efferent function in mice. Then, it reviews evidences showing that some drugs commonly used in clinical practice alter the efferent function (gentamicin, benzodiazepines, opiates, and quinoline derivates). Finally, it discusses the dopaminergic neurotransmission in LOC efferent fibers that has been reported to modulate the efferent function.

3.24.3.4.1 Knockout Mice (α9-nicotinic acetylcholine, αCGRP, $GABA_A$)

3.24.3.4.1.(i) α9-Nicotinic acetylcholine receptor knockout mice In 1999 Vetter and collaborators developed an α9-nicotinic acetylcholine receptor knockout mouse. Based on external examination, the α9-knockout mice had no evident phenotype; it presented a clear startle reflex and no difficulties with balance or movement. At a microscopic level, cochlear hair cells, supporting cells, and primary auditory neurons were not affected by the mutation and OC fibers, marked with choline-acetyltransferase inmunostaining, were seen at their normal crossing on the floor of the fourth ventricle. Efferent innervation was evaluated with specific antibodies against vesicular acetylcholine transporter or synaptophysin, an integral protein of the synaptic vesicle membrane. In knockout mice OHCs were innervated by one large efferent terminal instead of multiple smaller terminals as in wild-type mice; however, cholinergic innervation was present from base to apex in the cochlea.

Physiological tests in the α9-knockout mouse showed normal CAP thresholds across most of the hearing range and normal growth for CAP and DPOAE magnitudes with increasing intensity. However, these tests failed to show the best-known effect of OC activation, a reduction in cochlear sensitivity. Electrical stimulation of the crossed OC fibers at their crossing in the fourth ventricle did not elicit a decrease in CAP and DPOAE magnitudes in the α9-knockout, as in the wild-type mouse (Vetter, D. E. *et al.*, 1999). Several attempts have

been made to identify functional deficits in the α9-knockout, which could provide clues about the efferent-system functions. However, no significant differences were found between α9-knockout and control mice in behavioral thresholds for pure-tone detection and intensity discrimination under quiet conditions and in presence of noise (Prosen, C. A. *et al.*, 2000; May, B. J. *et al.*, 2002).

3.24.3.4.1.(ii) αCGRP knockout mice In an effort to learn about the role of the CGRP neuropeptide in the auditory function, Maison S. F. *et al.* (2003b) assessed auditory thresholds, input/output functions and MOC functions in mice in which the αCGRP receptor gene was deleted. No differences were found between wild type and αCGRP-null mice in auditory thresholds measured with auditory brainstem responses and DPOAEs. Also, the electrical activation of the MOC fibers at the fourth ventricle and the resistance to acoustic injury were similar in control and mutant mice. The αCGRP deletion did not affect the input/output functions for DPOAEs; however, it consistently reduced the amplitude of auditory-brainstem responses at suprathresholds sound levels. The authors concluded that the observed decrease in sound-evoked neural responses in the αCGRP knockout is most probably caused by the LOC system. The mechanism of action of CGRP in mammalian auditory efferents is unknown, but the activation of αCGRP receptors in myocites from the heart in rats increases the levels of cyclic adenosine monophosphate (cAMP), suggesting the presence of a G-protein-coupled receptor (Poyner, D. R. *et al.*, 1992).

3.24.3.4.1.(iii) $GABA_A$ receptor knockout mice Despite the clear evidence of the presence of GABA in both medial and lateral OC efferents, its functional role in the cochlea is still unknown. To elucidate the physiological function of this neurotransmitter, Maison S. F. *et al.* (2006) studied the cochlear phenotypes of seven lines of mice with targeted deletion of different $GABA_A$ receptor subunit genes. Four of the lines (α1, α2, α6, and δ) were found to be normal, without any sign of afferent or efferent cochlear histopathology or dysfunction. In contrast, mice with deletion on α5, β2, and β3 GABA subunits showed threshold elevations, decrease in efferent function or decreased density of efferent or afferent innervation. The authors concluded that the GABAergic component of OC innervation contributes to the long-term maintenance of cochlear hair cells and neurons.

3.24.3.4.2 Drugs that alter the auditory-efferent function

3.24.3.4.2.(i) Gentamicin Gentamicin is an aminoglycoside antibiotic that has well-known side effects as ototoxicity, nephrotoxicity and neuromuscular blockage. Brown R. D. (1972) (see also Brown, R. D. and Daigneault, E. A. 1973) showed that the suppressive effect of the electrical activation of OC fibers was reduced after a chronic systemic treatment with aminoglycosides, but he also observed some damage and loss of hair cells. Afterward, in a seminal work, Smith, D. W. *et al.* (1994) showed that a single dose of gentamicin (150 mg kg^{-1}) in awake guinea-pigs can block the reduction in CAP amplitude produced by activation of OC fibers by nonsimultaneous contralateral noise. This pharmacological effect, which did not affect CAP thresholds, was completely reversed after 72 h of the antibiotic treatment. Similarly, a single injection of gentamicin (150 mg kg^{-1}) abolished the suppression of DPOAE produced by contralateral white noise in awake guinea-pigs (Avan, P. *et al.*, 1996; Guitton, M. J. *et al.*, 2004). Gentamicin is believed to have pre- as well as postsynaptic effects in OHC efferent synapses. Aminoglycosides at a presynaptic level inhibit maxi-K^+ channels in isolated efferent auditory-nerve fibers (Takeuchi, S. and Wangemann, P., 1993) and at a postsynaptic level inhibit Ca^{2+} influx through voltage dependent calcium channels (Dulon, D. *et al.*, 1989) or via the α9/α10 nicotinic receptor, thus reducing the Ca^{2+}-activated K^+ currents in OHC (Blanchet, C. *et al.*, 2000; Rothlin, C. V. *et al.*, 2000).

Recordings of the unstimulated eighth-nerve ensemble background activity in awake guinea-pigs (Lima da Costa, D. *et al.*, 1997a; 1997b) showed different effects of gentamicin in the fast and slow suppression produced by contralateral acoustic activation of OC efferents (see Section 3.24.3.1.1.(ii)). The rapid OC effect was reversibly blocked by a single injection of gentamicin at a dose of 150 mg kg^{-1}, whereas higher doses were required to completely (although reversibly) block the slow effect, implying that these two effects may involve different cellular mechanisms. However, no dose dependency of the effect of gentamicin was found on the fast and slow effects of electrically evoked OC efferent activation in anesthetized guinea-pigs (Yoshida, N. *et al.*, 1999a). It is not clear whether the differences in the results of these two studies are due to the difference in OC efferent activation, contralateral sound versus electrical pulses at the fourth ventricle, or to the conditions of the animals, awake versus the deeply anesthetized.

Gentamicin has also been shown to block the efferent effects produced by electrical activation of the IC in anesthetized guinea-pigs (Popelar, J. *et al.*, 2002; Mulders, W. H. and Robertson, D., 2006). A single injection of gentamicin (210–250 mg kg^{-1}) abolished the efferent suppression of DPOAE produced by contralateral broadband noise and by electrical activation of the IC (Popelar, J. *et al.*, 2002). The administration of gentamicin, whether in a single injection (200 mg kg^{-1}) or by intracochlear perfusion, blocked the inhibitory and the excitatory effects produced by electrical activation of the IC (Mulders, W. H. and Robertson, D., 2006; Groff, J. A. and Liberman, M. C., 2003). These last results have been interpreted as suggesting that both the inhibitory as well as excitatory effects of the electrical stimulation of the IC are mediated by the MOC (Mulders, W. H. and Robertson, D., 2006).

3.24.3.4.2.(ii) Benzodiazepines Benzodiazepines are well-known drugs that potentiate the inhibitory chloride currents of GABA receptors in the nervous system. As discussed above, a group of GABAergic fibers that project to the OHCs has been identified in the MOC system. Velluti R. and Pedemonte M. (1986) showed in guinea-pig that systemic (i.p.) administration of benzodiazepines (chlordiazepoxide or midazolam) increases CAP amplitudes and reduces CM in a dose-dependent manner. These effects on cochlear potentials are opposite to those of electrical activation of the OC bundle, suggesting the presence of a tonic gabaergic activity on the cochlea. However, a later work in humans showed that oral intake of oxazepam (20 mg) does not affect the evoked OAEs (EOAEs) baseline amplitude, but produces a slight reduction in contralateral broadband noise suppression of EOAEs (Morand, N. *et al.*, 1998), indicating that benzodiazepines in humans can partially block the acoustic activation of the MOC system.

3.24.3.4.2.(iii) Opiod peptides It has been observed *in vitro* that morphine inhibits $\alpha 9$-nicotinic acetylcholine receptors and that the endogenous opioid peptides endomorphine-1 (μ-agonist) and dynorphine-B (κ-agonist) directly inhibit $\alpha 9/\alpha 10$ nicotinic acetylcholine receptors, by a mechanism not involving opioid receptors (Lioudyno, M. I. *et al.*, 2000; 2002). Intravenous administration of κ-agonist, μ-agonist (-)pentazocine in chinchillas produced a marked increase in CAP amplitude and no effect on CM (Sahley, T. L. *et al*, 1991, Sahley, T. L. and Nodar, R. H. 1994). Since this effect was blocked by the opiod antagonist naloxene, it must be mediated by opiod receptors located in LOC efferents (Sahley, T. L. *et al.*, 1996).

3.24.3.4.2.(iv) Quinoline derivates Quinine and chloroquine are medications commonly used in treatment of malaria. Their auditory side effects include sensorineural hearing loss and tinnitus (Jung, T. T. *et al.*, 1993). It has been shown *in vitro* that chloroquine and quinine block ACh-evoked currents in the $\alpha 9/\alpha 10$ nicotinic acetylcholine receptor through a competitive mechanism the former, and a mixed competitive and noncompetitive manner the latter (Ballestero, J. A. *et al.*, 2005).

3.24.3.4.3 Neurochemical and lesion studies of lateral olivocochlear transmission

Although the physiology of lateral efferents has remained elusive for many years, neurochemical and lesion studies have provided some clues about their physiological role, especially about the cochlear efferent function of dopamine.

3.24.3.4.3.(i) Neurochemistry of lateral olivocochlear dopaminergic transmission Intracochlear perfusion of dopamine in guinea-pigs reduced auditory-nerve CAP amplitudes, increased thresholds and decreased spontaneous and evoked auditory-nerve fiber activity, with no significant effect in CM amplitudes. It is known that dopamine acts on two types of receptors, D1- and D2-like receptors that activate and inhibit adenilate cyclase, respectively. Although antagonists to the two types of receptors had different effects in auditory-nerve units with different spontaneous rates, for low-spontaneous-rate fibers they increased spontaneous activity, improved threshold sensitivity and decreased maximum evoked firing rates, suggesting that dopamine in lateral efferents could exert a tonic inhibition on auditory-nerve activity (Ruel, J. *et al.*, 2001).

Inmunocytochemical evidence obtained in guinea-pigs strongly suggests the presence of dopamine in efferent varicosities that make synaptic contacts with afferent auditory dendrites postsynaptic to IHCs (D'Aldin, C. *et al.*, 1995). In the same study the intracochlear administration of piribedil, a D2-dopamine agonist, produced a dose-dependent decrease in auditory-nerve CAP amplitude that was more evident at high stimulus intensities. The fact that the D2 agonist produced no changes on CM potentials implied that the effect of dopamine does not involve OHCs.

Moreover, intracochlear perfusion of selective inhibitors of dopamine transporters, increased the cochlear dopamine level and diminished spontaneous and evoked neural activity, but had no effect on CM and DPOAE amplitudes (Ruel, J. *et al.*, 2006).

Electrical stimulation of cochlear tissue *in vitro* produced release of dopamine, which could be blocked by tetrodotoxin and cadmium, which inhibit axonal activity and Ca^{2+} influx respectively, indicating its neuronal origin. The dopamine release, probably from lateral efferents, could be modulated by D1, but not by D2, receptors (Gaborjan, A. *et al.*, 1999).

Niu X. and Canlon B. (2006) found by inmunohistochemistry that the D1 receptor is located at the auditory afferent dendrites and thus, that it is a postsynaptic target for dopamine released from lateral efferents. No differences were found in the distribution of D1 positively stained dendrites along the base, middle or apex of the cochlea. They showed that cochlear perfusion with a D1 agonist produced an increase in CAP amplitude, whereas perfusion with a D1 antagonist produced CAP reductions and increased CAP thresholds. Furthermore, they demonstrated that D1 effects on afferent fibers are mediated by a mechanism involving phosphorylation of glutamate receptors via protein kinase A/cAMP. They proposed a dual effect of dopamine; at high-level sounds D2 receptors would dominate and inhibit auditory nerve responses providing protection to acoustic injury (see Section 3.24.4.2.2), while at normal low-level sounds D1 receptors would dominate enhancing neural responses.

3.24.3.4.3.(ii) Selective lesions of lateral olivocochlear efferents In an attempt to selectively damage lateral efferents the cholinotoxin etylcholine aziridinium ion (AF64A) was injected into the cochlea in chinchillas. Cochlear infusion of 1 μM AF64A produced damage of lateral efferents, but not of MOC fibers or OHC, as evaluated 7 days after the injection by light and electron microscopy. Cochlear injection of 10 μM AF64A produced a significant disruption of LOC and MOC fibers, but also of cochlear supporting cells (Smith, D. W. *et al.*, 1989; Morley, B. J. *et al.*, 1991; Smith, D. W. and Mount, R. J., 1993). However, because cholinotoxin damages cholinergic neurons, it is difficult to rule out damage to MOC neurons.

Melittin, a cytotoxic chemical, has been used to selectively lesion the LOC nucleus in the guinea-pig brainstem finding a reduction in CAP amplitude, without changes in N1 latency (Le Prell, C. G. *et al.*, 2003). Adaptation of the DPOAEs, which is thought to be mediated by MOC efferents, was present in the severed animals, suggesting a selective lesion of lateral efferents. Although these results confirmed the notion that LOC efferents modulate eigth-nerve activity, it is not clear whether the ascending auditory pathway that passes through the lateral superior olive may also have been damaged.

Le Prell C. G. *et al.* (2005) used intracochlear administration of MPTP, a known dopaminergic toxin, to selectively disrupt the dopaminergic subset of LOC fibers in guinea-pigs. As in their study with LSO lesions (Le Prell, C. G. *et al.*, 2003), after disruption of LOC efferents they found CAP decreases at all tested frequencies (2–18 kHz) and CAP-threshold elevations at 16 and 18 kHz. The toxin applied to the cochlea affected neither amplitude nor adaptation of DPOAEs, leading to the conclusion that it did not affect OHC function, but selectively disrupted dopaminergic function of lateral efferents.

3.24.4 Proposed Functions of the Auditory Efferent System

The role of the auditory efferent system in hearing is still unknown. However, based on the available experimental evidence, various possible roles have been proposed for it. It has been suggested that the efferent system: (1) is involved in antimasking of auditory stimuli in noisy backgrounds, like in speech perception in noise; (2) has a protective role in preventing hearing loss caused by exposure to high-intensity sounds; (3) modulates cochlear sensitivity to filter unattended tones in auditory tasks or in tasks that require selective attention to stimuli of other sensory modalities; (4) modulates auditory afferent responses during sleep or awake states; and (5) could balance interaural sensitivity.

3.24.4.1 Antimasking of Auditory Stimuli in Noise

It has been suggested that the efferent system can enhance neural responses to acoustic stimuli in the presence of masking noise. Physiological and behavioral studies performed in animals and humans support this antimasking role of the efferent system, which, in humans, becomes quite important for the detection and discrimination of speech in noisy environments.

3.24.4.1.1 Antimasking in experimental animals

As described above (Section 3.24.3.3.1.(ii)), a chronic section of the OC bundle at the midline of the fourth-ventricle floor impairs, in the presence of background noise, intensity discrimination (May, B. J. and McQuone, S. J., 1995), sound localization (May, B. J. *et al.*, 2004), and human-speech sounds discrimination (Dewson, J. H., 3rd, 1968; Hienz, R. D. *et al.*,1998).

In acute physiological studies in guinea-pigs, it has been demonstrated that electrical stimulation of OC fibers at the midline of the fourth ventricle produces an antimasking effect, increasing neural responses to loud clicks recorded in the presence of masking noise (Nieder, P. and Nieder, I., 1970; Dolan, D. F. and Nuttall, A. L., 1988). Afterward, recording responses of auditory-nerve afferent fibers to tones in background noise, it was shown in cats that electrical stimulation of MOC fibers reduces the low-level noise-driven discharge rate and increases the saturation discharge rate (Winslow, R. L. and Sachs, M. B., 1987). Consequently, the effect of MOC electrical stimulation was to counteract the compression produced by broadband noise on auditory-nerve fiber discharge rate–level functions, improving the discriminability of the signal in the presence of background noise.

More recently, it has been shown in cats that the acoustic activation of efferent fibers also has an antimasking effect for sounds presented in the presence of noise (Kawase, T. and Liberman, M. C., 1993). The amplitude of the CAP elicited by a click presented together with an ipsilateral masker is larger in the presence of a simultaneous contralateral noise, which activates the OC efferents, than when the ipsilateral stimuli are presented alone (Figure 9). In these experiments, in some of the animals there was an enhancement of CAP responses during contralateral-noise stimulation even in the absence of an ipsilateral masker. This phenomenon was interpreted as a release from masking caused by internally generated sounds.

3.24.4.1.2 Antimasking of tones and speech in humans

The role of auditory efferents in the reduction of masking of sounds in noise has also been studied in human subjets. The OC efferent function can be assessed in humans by the magnitude of the suppression produced by contralateral noise in EOAEs (Collet, L. *et al.*, 1990; Moulin, A. *et al.*, 1993; see Section 3.24.3.2.2). In behavioral studies of

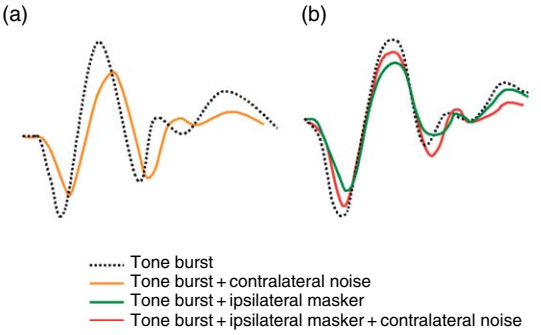

Figure 9 (a) Suppression of CAP by contralateral noise in quiet conditions (orange trace). (b) Antimasking effect of contralateral noise stimulation. An ipsilateral masker produces a CAP reduction (green trace). In this condition, the contralateral noise produces a CAP enhancement (red trace). In both panels, the segmented black traces indicate CAPs evoked with tone bursts alone. Adapted from Kawase, T. and Liberman, M. C. 1993. Antimasking effects of the olivocochlear reflex. I. Enhancement of compound action potentials to masked tones. J. Neurophysiol. 70, 2519–2532.

performance in detection and intensity discrimination of tones in noise, significant correlations have been reported between the magnitude of contralateral-noise suppression of EOAEs and the detection thresholds for a 2 kHz tone in noise, and the performance in intensity discriminations in noise (Micheyl, C. and Collet, L., 1996; Micheyl, C. *et al.*, 1997).

In other psychoacoustic tests, it has been shown that contralateral acoustic suppression also enhances speech perception in the presence of ipsilateral noise, and that the magnitude of the enhacement is correlated with the strength of the contralateral suppression of EOAEs, mediated by the efferent system (Giraud, A. L. *et al.*, 1997b; Kumar, U. A. and Vanaja, C. S., 2004). Furthermore, the same tests in patients in whom the efferent pathway had been sectioned (through vestibular neurotomy; see Section 3.24.3.3.1) showed almost no enhancement in word recognition in the de-efferented ear, but a greater enhancement in the healthy ear than that of normal subjects (Giraud, A. L. *et al.*, 1997b). In another study performed in vestibular neurotomized patients, little effect of the de-efferentation was found in pure-tone detection and frequency discrimination in quiet; however, several deficits of auditory perception in noise were found in most of the patients, such as worse intensity discrimination and speech recognition in noise (Zeng, F. G. *et al.*, 2000).

3.24.4.2 Protection to Loud Sounds

One of the proposed roles of the efferent system that has received more attention is its putative protection to acoustic injury from loud sounds. After the influential work by Cody A. R. and Johnstone B. M. (1982), showing that the losses in hearing sensitivity produced by an intense pure tone could be reduced by a tone of the same frequency simultaneously delivered to the contralateral ear, several other evidences have implicated the MOC system in protection to temporary hearing loss (Rajan, R. and Johnstone, B. M., 1988; Reiter, E. R. and Liberman, M. C., 1995) and to permanent hearing loss induced by loud sounds (Kujawa, S. G. and Liberman, M. C., 1997; Yamasoba, T. and Dolan, D. F., 1997). Recently, the LOC system has also been implicated in protection to temporary hearing loss (Darrow, K. N. *et al.*, 2007).

3.24.4.2.1 Medial olivocochlear protection to loud sounds

Electrical stimulation of the crossed OC fibers has been shown to reduce temporary thresholds shifts (TTSs) after brief exposures to high-intensity tones in anesthetized guinea-pigs. Crossed OC stimulation at any fixed rate produces the greatest reductions in TTSs for the exposures that would have caused the largest amounts of TTSs. On the other hand, OC electrical stimulation is always most effective when presented at a high rate and simultaneous with the exposure, and has a tonic effect that can last up to several minutes (Rajan, R., 1988a; 1988b). Electrical activation of the IC in guinea-pigs also produces a reduction of TTSs caused by loud sounds. Furthermore, chronic section or strychnine inactivation of the OC fibers increases the noise-induced permanent threshold shift in guinea-pigs and chinchillas (Kujawa, S. G. and Liberman, M. C., 1997; Zheng, X. Y. *et al.*, 1997a; 1997b; Yamasoba, T. and Dolan, D. F., 1997).

There is a high degree of intersubject variability in susceptibility to permanent hearing loss due to exposure to loud sounds, and it is known that some subjects have tough ears, whereas others have tender ears (Cody, A. R. and Robertson, D., 1983). Maison S. F. and Liberman M. C. (2000) found, in awake guinea-pigs, that the strength of sound-evoked efferent activity is inversely correlated with the degree of permanent hearing loss produced after an acoustic trauma. Moreover, a correlation has been found between cochlear expression of the $\alpha 9$ subunit of the cholinergic receptor and strength of the efferent function, thus implying that intersubject variability in vulnerability to noise damage may be partly caused by intersubject variability in $\alpha 9$ subunit cochlear expression (Luebke, A. E. and Foster, P. K., 2002). However, a previous study in guinea-pigs did not find any correlation between magnitude of the acoustic efferent reflex and susceptibility to TTSs (Zennaro, O. *et al.*, 1998).

There is also evidence in human subjects recovering from impulse noise trauma (young military subjects), suggesting that higher activity of the efferent system improves the short-term recovery of auditory thresholds (Veuillet, E. *et al.*, 2001a). In contrast, another study in human subjects participating in shooting exercises did not find any correlation between acoustic contralateral suppression of DPOAEs and susceptibility to TTSs (Wagner, W. *et al.*, 2005).

In a study aimed to determine whether the putative OC protective effect to acoustic trauma was mediated by the $\alpha 9$ nicotinic receptor, hearing was assessed after noise exposure in $\alpha 9$-knockout mice (129/SvEv strain). No differences in permanent threshold shift were found between homozygotes, heterozygotes, and wild-type mice a week after exposure to high-intensity broadband noise (Yoshida, N. *et al.*, 1999b). However, the 129/SvEv mice strain used to generate the $\alpha 9$-knockout mice (Vetter, D. E. *et al.*, 1999) tested for vulnerability to acoustic injury was later shown to be exceptionally resistant to noise-induced hearing loss (Yoshida, N. *et al.*, 2000). The special characteristic of high resistance to acoustic injury observed on this mice strain must reflect mechanisms other than those involving the $\alpha 9$-nicotinic receptor. More recent evidence supports the idea that OC protection to acoustic trauma is mediated by the $\alpha 9$ nicotinic receptor. Overexpression of the $\alpha 9$ nicotinic receptor has been shown to increase MOC suppression effects in the cochlea and to enhance ear protection to temporary and permanent acoustic trauma in mice, without changes in auditory thresholds (Maison,S. F. *et al.*, 2002).

The time course of the protective effect from acoustic trauma, and the exposure frequencies at which it is more effective (10 kHz) suggest that the slow rather than fast effect of OC activation is responsible for this protective effect (Reiter, E. R. and Liberman, M. C., 1995). Recently, Maison S. F. *et al* (2007b) studied mice overexpressing the SK2 channel (Ca^{2+}-activated K^+ channel; see Section

3.24.2.1.3; Figure 2) in OHCs, finding that cochlear morphology, auditory thresholds, and OAEs were normal, but electrically evoked fast efferent suppression was enhanced, similarly as in $\alpha 9$ nicotinic-receptor overexpresser mice (Maison, S. F. *et al.*, 2002). These mice, however, did not show enhanced resistance to acoustic trauma, suggesting that the efferent protective effects from acoustic overexposure are not dependent on the function of the SK2 channel and probably depend on other cellular mechanisms activated by Ca^{2+} entry into OHCs.

3.24.4.2.2 Lateral olivocochlear protection to loud sounds

It has been proposed that the release of dopamine by the lateral efferents could have a functional role in the postsynaptic regulation of the glutamatergic activity of IHCs and in mediating a protection of auditory nerve dendrites against loud sounds that induce massive releases of glutamate from IHCs and produce swelling of auditory nerve fibers (D'Aldin, C. *et al.*, 1995; Oestreicher, E. *et al.*, 1997; Niu, X. and Canlon, B., 2002; Niu, X. *et al.*, 2004).

Niu X. and Canlon B. (2002) found an up-regulation of tyrosine-hydroxylase-positive efferent terminals on the guinea-pig cochlea during sound preconditioning (the protective effect of exposure to low-level sounds against a subsequent exposure to loud sounds), and that the protective effects of preconditioning can be blocked by 6-hydroxidydopamine, which disrupts tyrosine hidroxylase in the lateral efferent terminals. These results suggest a role of lateral efferents in protection to acoustic trauma by sound conditioning.

Selective, unilateral destruction of the LSO by stereotaxically injected melittin in mice increased the ipsilateral frequency- and level-independent suprathreshold auditory-nerve component (wave 1) of brainstem responses, with no evident simultaneous changes in DPOAE amplitudes (Darrow, K. N. *et al*, 2007). In these mice, exposure to an acoustic trauma produced greater TTSs in neural responses from the cochlea ipsilateral than contralateral to the LSO lesion.

Consequently, both, the medial and lateral, components of the efferent system seem to be involved in protection to acoustic injury by loud sounds. However, it is unlikely that the auditory efferent system may have evolved primarily as a protective mechanism from acoustic trauma, because it has been present in vertebrates for millions of years of evolution, while high-intensity sounds are rarely found in nature, and they only appeared in the last 200 years of human history, after the industrial revolution (Kirk, E. C. and Smith, D. W., 2003).

3.24.4.3 Modulation of Sensory Input During Sleep

Significant increases in CM and auditory-nerve CAPs have been found in guinea-pigs during slow wave sleep, as compared to in the awake state and in paradoxical sleep (Velluti, R. *et al.*, 1989). In these experiments the changes in both cochlear potentials could not be attributed to middle-ear muscle reflex, because the middle-ear ossicles and muscles were removed and auditory stimuli were directly delivered to the animal's bulla. These results imply that during sleep the central nervous system modulates auditory input through OC efferents. A single systemic injection of gentamicin ($150\,mg\,kg^{-1}$) that blocks MOC efferent effects in unanesthetized guinea-pigs (see Section 3.24.3.4.2.(i)) did not affect the central modulations of cochlear responses produced through OC efferents by sleep/awake state changes (Pedemonte, M. *et al.*, 2004). However, it is possible that the gentamicin dose used in these experiments was too low to block the efferent effect, and a higher dose may be required. This was the case for the slow suppression produced by contralateral-sound activation of OC efferents that was not blocked by a single dose of $150\,mg\,kg^{-1}$ gentamicin, but was completely blocked by a $250\,mg\,kg^{-1}$ dose (Lima da Costa, D. *et al.*, 1997a).

In relation to humans, Campbell K. B. and Bartoli E. A. (1986) did not find any reliable differences in the amplitude or latency of brainstem auditory evoked potentials recorded during wakefulness and various stages of sleep. A later study, recording TEOAE during sleep in adults found a progressive increase in TEOAE amplitudes through the night that could reach up to 4 dB at the end of the night, but that was not related to the sleep stages (Froehlich, P. *et al.*, 1993). The work also evaluated the effect of contralateral noise on the amplitude of TEOAE and found a decrease in the reduction of TEOAEs by contralateral noise during the night. Although this study suggests a role of auditory efferents during sleep, another factor that could also modify the magnitude of TEOAEs, as middle-ear muscle activity, was not excluded.

3.24.4.4 Modulation of Cochlear Sensitivity by Selective Attention

Hernandez-Peón *et al.* (1956) showed a reduction in click-evoked potentials recorded from the cochlear nucleus in cats while receiving stimuli of other sensory modalities. They postulated the existence of peripheral filters that would selectively inhibit unattended inputs at early stages of the sensory pathways. This proposition became controversial as other groups fail to replicate their findings (Dunlop, C. W. *et al.*, 1965; Wickelgren, W. O., 1968). However, later experiments confirmed the hypothesis that cross-modal attention to visual stimuli could attenuate peripheral auditory responses, as reductions in CAP amplitude were found in cats attending to visual stimuli (Oatman, L. C., 1971).

3.24.4.4.1 Cross-modal attenuation of auditory stimuli

Reductions in the amplitude of CAP responses during periods of visual attention have been demonstrated in cats and chinchillas performing visual discrimination tasks (Oatman, L. C., 1971; Delano, P. H. *et al.*, 2007). Similarly, in humans, the auditory-nerve component of tone-pip evoked brainstem potentials were significantly reduced in subjects when instructed to count letters flashed on a screen (Lukas, J. H., 1980). In another study in humans, attention to a visual task produced a small but significant amplitude decrease of click-evoked OAEs, indicating changes in cochlear mechanics (Puel, J. L. *et al.*, 1988).

Recently, it has been shown, in chinchillas performing a visual discrimination task, that reductions of CAP amplitude during periods of visual attention are also accompanied by increases in CM amplitude (Figure 10; Delano, P. H. *et al.*, 2007). Two facts are worth mentioning in these results: (1) The reduction of cochlear sensitivity is transient (a few seconds), during the period of high expectancy; and (2) the reduction of cochlear sensitivity is larger for higher attentional loads of the task (shorter target stimuli). These facts could probably explain why some works have failed to find a reduction of cochlear sensitivity during visual attention. An easy task or an inadequate temporal resolution of the method to assess cochlear responses can lead to negative results.

Auditory efferents are most probably involved in this cochlear cross-modal attentional effect. Sectioning the tendons of the middle-ear muscles did not abolish this effect (Oatman, L. C., 1971) and increases in CM amplitudes simultaneous with CAP reductions are incompatible with a middle-ear muscle effect (Delano, P. H. *et al.*, 2007). Also, the CAP amplitude reductions concomitant to CM increases observed in the cross-modal attentional effect are reminiscent of the efferent effects produced by electrically evoked activation of MOC fibers (Gifford, M. L. and Guinan, J. J., Jr., 1987).

3.24.4.4.2 Intra-modal frequency filter

There is experimental evidence in anesthetized animals of a frequency-dependent loss of sensitivity in basilar membrane vibrations during efferent stimulation (Murugasu, E. and Russell, I. J., 1996a; Dolan, D. F. *et al.*, 1997) that could account for similar neural effects (Robles, L and Ruggero, M. A., 2001). Likewise, psychophysical measurements in humans show frequency-specific effects of attention in detection of target tones of unexpected frequencies in noise (Greenberg, G. Z. and Larkin, W. D., 1968). Furthermore, humans in whom the auditory efferent pathway has been sectioned present higher detection levels of unexpected target frequencies in noise than before surgery (Scharf, B. *et al.*, 1994; 1997), suggesting that the efferent system is required to maintain an attentional band-pass filter.

3.24.4.5 Balance of Interaural Sensitivity

Recently, Darrow K. N. *et al.* (2006b) suggested a new role for the LOC efferents. Using the protocol mentioned above (see Section 3.24.3.4.3.(ii)), in which an injection of melittin selectively destroys LSO cells, they reported that in mice in which LSO cells were effectively destroyed there was an amplitude increase of wave 1 of the auditory brainstem responses, without changes in DPOAE amplitudes. Surprisingly, they also found an amplitude reduction in the contralateral wave 1 of the auditory brainstem response. As it is known that LSO neurons are involved in processing interaural intensity differences for sound localization, they proposed that the LOC system may provide a binaural sensitivity balance required for accurate sound localization.

3.24.5 Some Clinical Findings

Little is known about the involvement of the auditory efferent system in clinical pathologies. Only a few findings have been reported about its

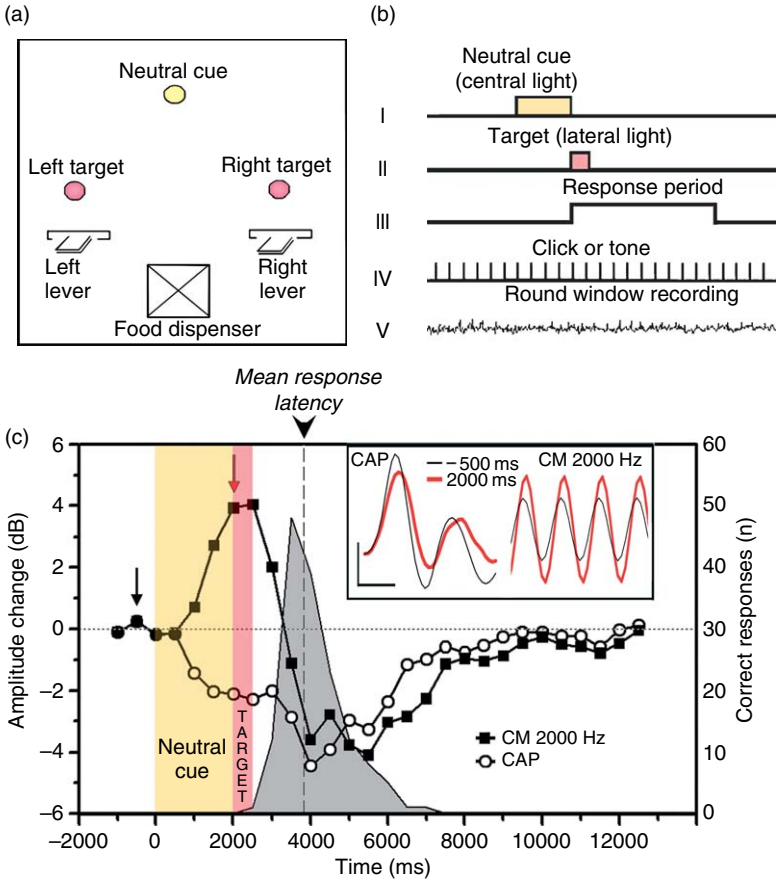

Figure 10 Reduction of cochlear sensitivity during visual attention. (a) Schematic diagram of the frontal panel of the operant cage used in the visual discrimination task. (b) Time sequence of this task. I–III: A neutral cue (central light) was turned on before one of two lateral lights (targets); the chinchilla had 5 s to respond by pressing a lever under the target light. IV: Simultaneously an irrelevant click and/or tone train was presented at 2 Hz rate. V: The round-window electrical signal was acquired during the task. (c) Example of CM augmentation (solid squares) concomitant to CAP reductions (open circles) during the period of visual attention. Symbols on each trace represent CAP and CM amplitude changes measured in dB, referenced to the average amplitude of the respective cochlear potential measured before the onset of the neutral cue. The figure also shows a histogram for the latencies of correct responses to the target (dark gray shaded area; scale in right *y*-axis). The upper-right inset shows examples of averaged CAP and CM traces from −500 ms (thin trace) and 2000 ms (thick trace) (see vertical arrows in panel (c); scale bar: *x*-axis: 0.5 ms; *y*-axis: 40 μV for CAP, 80 μV for CM). The mean correct-response latency measured from the target-light onset was 1833 ms (vertical segmented line). Adapted from Delano, P. H., Elgueda, D., Hamame, C. M., and Robles, L. 2007. Selective attention to visual stimuli reduces cochlear sensitivity in chinchillas. J. Neurosci. 27, 4146–4153.

possible role in some auditory and psychiatric disorders and in myasthenia gravis disease.

A dysfunction of auditory efferents has been postulated in the physiopathology of acute tinnitus, although diverse results have been obtained by different groups (Chery-Croze, S. *et al.*, 1993; Riga, M. *et al.*, 2007). Significantly lower efferent suppression of EOAEs was reported in children with impaired learning than in normal children (Veuillet, E. *et al.*, 1999); however, no difference was found in efferent activity between children with specific language impairments and controls (Clarke, E. M. *et al.*, 2006).

Auditory efferent dysfunctions have been found in relation to some behavioral disorders. A decrease in acoustically evoked efferent activity and differences in the right–left asymmetry of efferent suppression have been reported in subjects with autism and in schizophrenic patients (Collet, L. *et al.*, 1993; Khalfa, S. *et al.*, 2001b; Veuillet, E. *et al.*, 2001b). A reduction in auditory efferent activity has also been found in some children with selective mutism, a

psychiatric disorder in which patients are reluctant or not able to speak in specific situations (Bar-Haim, Y. *et al.*, 2004).

The possible involvement of cochlear-efferent nicotinic-ACh receptors in patients affected by myasthenia gravis has been reported by several authors. Myasthenia gravis is an autoimmune neuromuscular disease characterized by the presence of circulating antibodies against nicotinic acetylcholine receptors, in which patients have muscle weakness and fatigability. Myasthenic patients present significantly reduced levels of DPOAEs, TEOAEs, and efferent activity before pharmacological treatment, which after administration of acetylcholinesterase inhibitors recover almost control levels (Toth, L. *et al.*, 1998; Paludetti, G. *et al.*, 2001; Di Girolamo, W. *et al.*, 2001); however, chronic myasthenic patients develop a permanent cochlear efferent damage (Hamed, S. A. *et al.*, 2006). Based on these findings, it has been suggested that recordings of OAE may be useful in early diagnosis and in the evaluation of treatments in some forms of myasthenia gravis.

3.24.6 Conclusions

The evidence reviewed in this chapter shows a significant presence of efferent auditory pathways that originate in the auditory cortex, project to various levels of the afferent auditory path, and reach as far as the cochlea. An important number of efferent nerve fibers make direct synaptic contact with cochlear hair cells and dendrites of auditory nerve cells. This significant efferent innervation makes possible a tight top-down control on incoming auditory information. However, despite the clear evidence showing that activation of the efferent fibers produces mainly suppressive effects on cochlear responses, the function of the efferent system in audition is still uncertain. Probably, the difficulty found in the assessment of the auditory deficits produced by lesions of the efferent system in experimental animals and in humans, made more difficult to resolve the role of the efferent system in audition. Among the various functions that have been proposed for the auditory efferent system, three of them have concentrated most of the research efforts: cochlear protection to acoustic trauma, antimasking of sound in noise, and modulation of cochlear sensitivity by selective attention. In the first of these, acoustical activation of a reflex circuit comprising the brainstem prevents hearing losses caused by exposure to loud sounds. In the latter two functions, which are closely related, top-down neural pathways originating in the auditory cortex modulate cochlear sensitivity at particular times or for specific frequencies, making it possible to unmask sounds in noisy environments or to attend to specific stimuli.

Glossary

air–bone gap The difference between air- and bone-conduction hearing thresholds at specific frequencies.

assistive listening device (ALD) Any device, such as a hearing aid, designed to be worn or used to improve hearing.

aural rehabilitation Nonmedical/surgical approaches designed to overcome/help minimize the effects of hearing loss on communication and quality-of-life.

autoimmune Pertaining to disorders of the body's immune system.

bone-anchored hearing aid (BAHA) A hearing aid implanted behind the ear designed to bypass the conductive portion of the auditory system and deliver sound to the inner ear via bone conduction.

cochlear implant An electronic device implanted into the inner ear designed to provide electrical stimulation to the auditory nerve in response to sound.

conductive hearing loss Hearing loss that prevents the transmission of sound to the inner ear.

mixed hearing loss Hearing loss that includes both conductive and sensorineural components.

myringotomy A tiny surgical incision made in the tympanic membrane under microscopy that permits drainage of the middle ear and/or placement of a pressure equalization tube.

ossiculoplasty Surgical reconstruction of the ossicular chain.

ototoxic/ototoxicity Pertaining to pharmaceutical agents or other chemicals that are toxic to hearing.

pharmacological Pertaining to the use of pharmaceutical agents in the treatment of hearing loss.

sensorineural hearing loss Hearing loss that involves the inner ear (cochlea) and/or auditory nerve.

stapedectomy A surgical procedure for the treatment of otosclerosis that involves removing the stapes and replacing it with a prosthetic device.

tympanoplasty A surgical procedure to heal chronic perforations of the tympanic membrane.

3.25.1 Introduction

Disorders of the auditory system have become prevalent in modern society due to the combined effects of noise, aging, disease, and heredity. Approximately 28 million Americans have hearing loss, with this number expected to rapidly climb and nearly double by 2030 (National Institute on Deafness and Other Communication Disorders, 1996). A primary reason for this prediction is that the incidence of hearing loss increases with age, and older Americans constitute the fastest growing segment of the population. For adults over the age of 65 years, hearing disorders represent the third most prevalent chronic condition, ranking behind only arthritis and hypertension as primary health concerns (Brechtelsbauer, D. A., 1990).

The most common causes of hearing loss in adults are presbyacusis (hearing loss related to aging) and noise exposure. The most significant consequences of decreased hearing are increased difficulty understanding speech, and the effects of this condition on communication. If left untreated, adults experience social/emotional difficulties, such as increased stress, anger, guilt, depression, anxiety, and withdrawal (Chartrand, M. S., 1990). This situation is cause for considerable concern since only approximately 20% of the total adult hearing-impaired population owns hearing aids, and many of these individuals may not be using their aids correctly, or at all (Kochkin, S., 2002).

Genetic/hereditary factors and middle ear pathology constitute the most common causes of hearing loss in children. It is well recognized that normal auditory function is essential for normal speech and language development, communication, and learning. Therefore, early identification of hearing loss in children is critical. If left unidentified and untreated, hearing loss causes delay in development of receptive and expressive communication, reduced academic achievement, and can lead to social isolation and poor self-concept. These disabilities can be minimized by early intervention.

Traditionally, hearing loss has been classified into three categories or types: conductive, sensorineural, and mixed. Conductive disorders are conditions that prevent sound waves from reaching the inner ear. Sensorineural disorders involve the cochlea and/or auditory nerve, while mixed hearing losses include both conductive and sensorineural components.

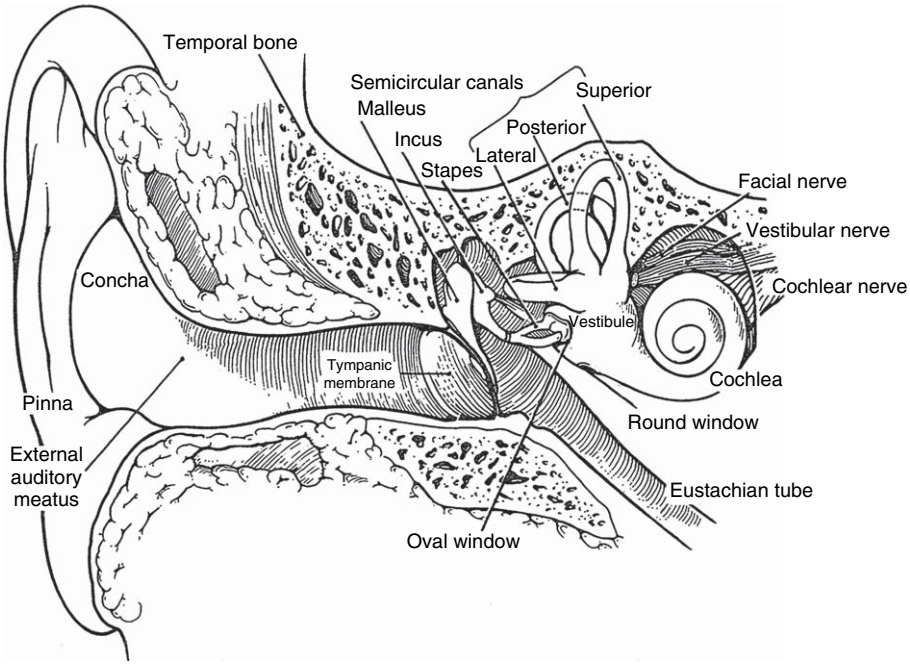

Figure 1 Schematic of the human peripheral auditory system. From Bess, F. H. and Humes, L. E. 2003. Audiology: the Fundamentals, 3rd edn. Lippincott Williams & Wilkins.

Conductive losses traditionally have been considered as treatable through medical and/or surgical approaches. Examples include the treatment of otitis media with antibiotics and the reconstruction of the tympanic membrane for perforations. Sensorineural hearing losses such as those caused by noise exposure or presbyacusis have largely been managed by amplification. This paradigm is slowly changing with the appreciation that a number of complex inner ear diseases that include sensorineural hearing loss as a manifestation are actually treatable through pharmacologic intervention. In addition to progress in the pharmacologic treatment of inner ear disease, significant advances in the surgical treatment of hearing loss have been made in the area of cochlear implantation. Cochlear implants now offer the clinician the ability to rehabilitate profoundly hearing-impaired patients. Development of bilateral implantation and the utilization of hybrid devices in which patients use a cochlear implant in conjunction with residual hearing are further improving outcomes.

Figure 1 displays a drawing of the auditory periphery. This figure can be used as a reference for the anatomical sites/structures that may be involved in the various types of hearing loss described in this chapter as well as the areas where treatments are focused.

Degree of hearing loss refers to the severity of the loss. Table 1 identifies the five broad categories that are typically used to classify the degree of loss. The numbers displayed represent hearing thresholds (i.e., the lowest intensity of sound that is perceived at least 50% of the time). A key indicator of posttreatment outcome is the level to which the degree of loss has improved.

The treatment of hearing loss varies considerably according to the cause (if known), type, and degree of impairment. Generally, these approaches can be categorized as either medical/surgical or nonmedical/nonsurgical. This chapter will provide an overview of current treatments under these two broad categories.

Table 1 Classification of hearing loss according to degree

Hearing threshold in dB HL	*Degree of loss classification*
0–15	Normal
16–25	Slight
26–40	Mild
41–55	Moderate
56–70	Moderately severe
71–90	Severe
>90	Profound

3.25.2 Medical/Surgical Treatments

3.25.2.1 Conductive Hearing Loss

As indicated above, conductive hearing loss is the impairment or loss of transmission of sound to the inner ear. Normally, the coordinated action of the external auditory canal (EAC), tympanic membrane, and ossicular chain amplify sound entering the EAC by as much as 30 dB as it is delivered to the inner ear. This phenomenon occurs through a combination of factors, including resonance of the EAC, the ratio of the surface areas of the tympanic membrane to oval window opening, and the mechanical lever action of the ossicular chain. Pure tone audiometry, assessing both air conduction and bone conduction, can measure the degree of conductive hearing loss by determining the difference between air conduction and bone conduction hearing thresholds at specific frequencies. This difference is termed the air–bone gap. A key indicator of posttreatment outcome for conductive losses is the degree to which the air–bone gap has been closed. Although lacking in precision, various tuning fork tests also can be applied to gain quick insight as to whether or not hearing loss is conductive in nature. Tympanometry is another tooluseful in the identification of conductive hearing loss.

As overviewed in Table 2, multiple etiologies of conductive hearing loss exist. The following section will include a description of treatment options for managing, and often curing the more common causes of such disorders.

Table 2 Common etiologies for conductive hearing loss

External ear
- Cerumen impaction
- Congenital aural atresia
- Exostoses
- Foreign body
- Otitis externa
- Tumor of the external auditory canal

Middle ear
- Acute otitis media
- Cholesteatoma
- Glomus tumor
- Mastoiditis
- Osteogenesis imperfects
- Otosclerosis
- Paget's disease
- Serous otitis media
- Temporal bone trauma
- Tympanic membrane perforation

3.25.2.1.1 Debridement of the ear canal

Perhaps the most common form of acquired conductive hearing loss in adults is cerumen impaction. Although the EAC is normally self-cleaning, abnormal narrowing of the canal, whether congenital or acquired from a variety of factors, including multiple bouts of otitis externa, can retard the ear's natural ability to eliminate cerumen buildup. This situation can lead to deposition and, eventually, complete occlusion of the EAC. In addition, use of cotton-tipped applicators can push cerumen deep into the canal leading to compaction, analogous to packing the barrel of a cannon. Fortunately, removal of the cerumen by a physician or audiologist via debridement (irrigation/suction or curettage under microscopic examination) of the ear canal readily reverses the associated conductive hearing loss.

3.25.2.1.2 Myringotomy and pressure equalization tube placement

A myringotomy is a tiny surgical incision made in the tympanic membrane under microscopy that permits placement of a pressure equalization tube. Pressure equalization tubes allow the middle ear space to ventilate via the EAC and significantly reduce complications from Eustachian tube dysfunction and resolve any associated conductive hearing loss. Indications for this procedure include chronic Eustachian tube dysfunction, multiple episodes of acute otitis media (AOM), and chronic serous otitis media (described below).

3.25.2.1.3 Tympanoplasty

A tympanoplasty is a surgical procedure to heal chronic tympanic membrane perforations. An incision is made behind the ear or through the EAC skin and the remaining tympanic membrane is elevated. A graft, most commonly postauricular fascia, is then placed lateral to the head of the malleus and either medial or lateral to the native tympanic membrane. The graft is secured in place by packing the EAC with small gelatin sponges. If the etiology of the tympanic membrane perforation is infectious causes, tympanoplasty often is performed in combination with a mastoidectomy, a procedure that removes diseased tissue from the mastoid air cells and helps improve aeration of the middle ear space. Approximately 90–95% of patients who

undergo a tympanoplasty will obtain complete closure of the perforation with an accompanying reduction of the air–bone gap. Should the first operation fail to heal the perforation completely, additional attempts using the same procedure can be made.

3.25.2.1.4 Pharmacological treatments

AOM (described below) can cause a conductive hearing loss secondary to fluid present behind the tympanic membrane. In 2000, there were 16 million physician office visits in the USA for AOM (Cherry, D. K. and Woodwell, D. A., 2002). Prescriptions for antibiotics were given in approximately 80% of these visits. Common pathogens cultured from infected ears in AOM include *Streptococcus pneumonia* (25–50%), nontypeable *Haemophilus influenzae* (15–30%), and *Moraxella catarrhalis* (3–20%; Klein, J. O., 1994). A current recommendation for initial antibiotic treatment is amoxicillin, a penicillin analog, with or without clavulanate (American Academy of Pediatrics Subcommittee on Management of Acute Otitis Media, 2004). In patients who are penicillin allergic, other options include cephalosporins, clindamycin, or macrolide antibiotics. In general, treatment is given for 7–10 days to eradicate the pathogen completely and resolve the middle ear effusion.

Myringotomy, pressure-equalization tubes, tympanoplasty, and antibiotics are used to treat a variety of middle ear disorders. Some of the more common ones are described below.

3.25.2.1.5 Eustachian tube dysfunction

The Eustachian tube is a bony and fibrocartilaginous structure that connects the middle ear space with the nasopharnyx and functions to regulate the middle ear pressure to maintain equilibrium between −50 mm H_2O and +150 mm H_2O. Under normal conditions, the middle ear mucosa absorbs gases contained within the middle ear space creating negative air pressure (Bluestone, C. D. *et al.*, 2005). To maintain equilibrium, the Eustachian tube opens in the nasopharnyx and permits movement of air into the middle ear space to compensate for air-pressure changes. If the Eustachian tube fails to open, continued negative middle ear pressure impairs tympanic membrane mobility and reduces mechanical transmission of sound through the ossicular chain. This phenomenon is commonly observed when ascending or descending in an airplane, creating a temporary conductive hearing loss which resolves once the Eustachian tubes open. Several factors can impair the ability of the Eustachian tube to open, including rapid weight loss causing a patulous Eustachian tube (Tideholm, B. *et al.*, 1999), congenital disorders such as cleft palate, and obstruction of the opening of the Eustachian tube observed with adenoidal hypertrophy in children. Chronic decreased middle ear pressure as a result of Eustachian tube dysfunction lead to retraction of the tympanic membrane, which in severe cases is adherent to the middle ear mucosa.

3.25.2.1.6 Otitis media

Otitis media is the collection of fluid behind the tympanic membrane. The pathophysiology is often related to Eustachian tube dysfunction that leads to serous fluid accumulation from the surrounding middle ear mucosa (Bluestone, C. D. *et al.*, 2005). This fluid results in impaired vibration of the ossicles. In AOM, the fluid can become infected from nasopharyngeal flora leading to acute suppurative otitis media, which is common in children. This condition is exacerbated by the relatively short length of the pediatric Eustachian tube in combination with retrograde reflux of nasopharyngeal contents through the Eustachian tube into the middle ear space (Tasker, A. *et al.*, 2002; Bluestone, C. D. *et al.*, 2005). Chronic serous otitis media is a condition in which the fluid is benign and persists for greater than 1 month. If this fluid becomes infected, the term chronic suppurative otitis media is applied. As children grow, the Eustachian tube develops a more anterior and inferior course which prohibits Eustachian tube reflux as well as allows better opening of the nasopharyngeal opening of the Eustachian tube to permit gas exchange with the middle ear space (Daly, K. A. *et al.*, 2005). Diagnosis is made clinically by inspection of the tympanic membrane and can be augmented with audiometric tympanometry, with characteristic findings of a flattened tympanogram.

3.25.2.1.7 Perforation of the tympanic membrane

Trauma, acute or chronic otitis media, Eustachian tube dysfunction, and a variety of other conditions can cause a tear in the tympanic membrane which is usually preceded by severe pain (Boedts, D., 1995). Diagnosis is made by inspection of the tympanic membrane during

otoscopy. Depending on its size and location, a perforation can lead to a conductive hearing impairment. Fortunately, the majority of tympanic membrane perforations heal spontaneously. For perforations refractory to conservative management, tympanoplasty can be performed to correct the defect and help restore hearing.

3.25.2.1.8 Stapedectomy

Stapedectomy is a short outpatient surgical procedure, usually lasting 60–90 min, for the treatment of otosclerosis (described below). During this procedure, the tympanic membrane is reflected anteriorly through a postauricular or EAC surgical approach. After confirming fixation of the stapes at the oval window, the incudostapedial joint is separated and the stapes is fractured at the footplate using a laser. A small hole is made in the center of the stapes with the laser and prosthesis is placed over the oval window and secured to the incus. After confirming complete mobility of the ossicular chain, a small soft tissue graft is placed around the prosthesis and the tympanic membrane returned to its anatomical position and the EAC packed with small gelatin sponges. Approximately 90% of individuals with otosclerosis will achieve reduction of the air–bone gap to <10 dB.

3.25.2.1.9 Ossicular chain reconstruction

Ossicular erosion, discontinuity, or fixation is most commonly caused by cholesteatoma (described below) or chronic suppurative otitis media. With complete disruption of the ossicular chain, conductive hearing losses as high as 60 dB are observed, but ossicular chain discontinuity should be suspected in any individual with an air–bone gap greater than 30 dB. Ossicular chain reconstruction, termed ossiculoplasty, is a surgical procedure performed to improve the conductive portion of hearing loss. After removal of diseased tissue, including affected portions of the ossicular chain, grafts are placed to replicate the eroded ossicles. The type of graft used is determined by the extent and location of disease as well as the preference of the surgeon. Common grafts include autogenous cartilage and hydroxyapatite incorporated materials. Successful reconstruction can achieve air–bone gap closure to within 5–10 dB.

Stapedectomy and ossicular chain reconstruction generally are used to treat otosclerosis and cholesteatomas, which are described below. Both of these conditions cause conductive hearing loss.

3.25.2.1.10 Otosclerosis

The most common form of congenital conductive hearing disorder is otosclerosis. The hallmark of this disease is abnormal bone growth in portions of the ossicular chain. The most common location of bone deposition is around the stapes footplate, which can progress to eventual fixation of the footplate. Once the stapes footplate is fixated, mechanical sound transmission through the oval window is prohibited. Approximately 10% of Caucasians have histological evidence of otosclerosis at autopsy, but only 10% of these individuals have clinical evidence of disease (Cole, R. A. and McKenna, M., 2001). African Americans are affected less, with only 1% having histological evidence at autopsy. Women are affected more frequently than men with a 2:1 ratio. A characteristic finding in patients with otosclerosis is the Carhart notch. This finding is denoted by an apparent sensorineural hearing loss of 20–30 dB at 2000 Hz by audiometry. Interestingly, this finding disappears after surgical correction of otosclerosis, and does not represent a true sensorineural hearing loss in affected individuals. Patients with a reversed tuning fork test by Rinne examination, showing bone conduction better than air conduction when using the 512-Hz and 1024-Hz tuning forks, are best candidates for surgery. Surgical options include stapedectomy or stapedotomy plus placement of prosthesis.

3.25.2.1.11 Cholesteatoma

Cholesteatomas are congenital or acquired destructive lesions of the temporal bone. These lesions consist of squamous epithelium trapped within the skull base that slowly grows and erodes into surrounding structures (Kazahaya, K. and Potsic, W. P., 2004). Drainage from the ear, termed otorrhea, often is observed in the affected ear. In advanced disease, the erosion of the incus and malleus leads to a conductive hearing loss often greater than 30 dB. Surgery is performed to remove the cholesteatoma with reconstruction of the ossicular chain to restore hearing and reduce the air–bone gap.

Many of the conditions described above affect the appearance of the tympanic membrane. Figure 2 shows otoscopic photographs of a normal tympanic membrane along with tympanic membranes affected by different conductive disorders.

3.25.2.1.12 Bone-anchored hearing aid

A bone-anchored hearing aid (BAHA) is an implantable hearing aid that consists of three parts: (1) an

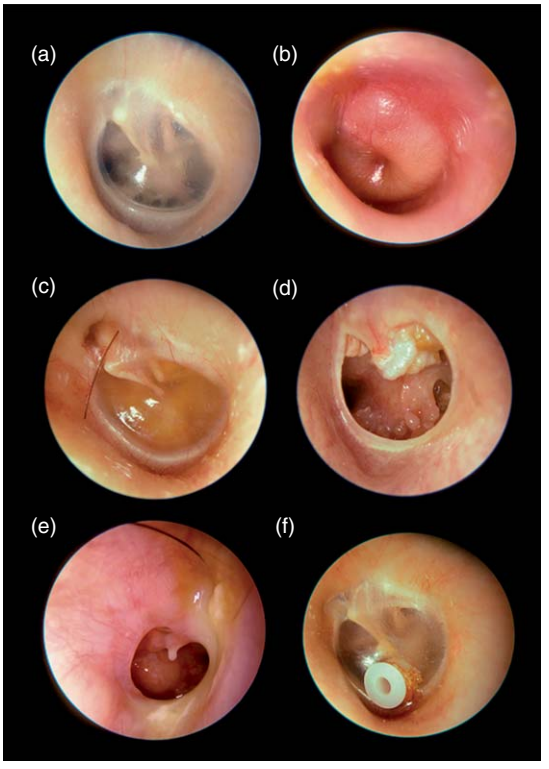

Figure 2 Otoscopic view of (a) normal tympanic membrane, (b) acute otitis media, (c) chronic serous otitis media, (d) cholesteatoma, (e) tympanic membrane perforation, and (f) myringotomy with pressure equalization tube placement. Reproduced from http://me.hawkelibrary.com, with permission.

implanted titanium screw placed behind the ear, (2) an abutment attached to the screw and visible on the surface of the skin, and (3) an external sound processor (Snik, A. F. *et al.*, 2005). The BAHA has been approved by the US Food and Drug Administration (FDA) for conductive and mixed hearing loss and more recently for unilateral sensorineural hearing loss. The device acts by translating sound into bone vibration at the site of the implant. Vibration is then conducted through bone to stimulate the cochlea directly, completely bypassing the middle ear. Since the BAHA is attached to an abutment behind the ear with no portion contained within the EAC, a variety of individuals can benefit from this device, including patients with congenital EAC atresia, chronic otitis externa or otitis media, or individuals unable to tolerate conventional hearing aids. Moreover, when the BAHA is implanted behind the affected ear in patients with unilateral profound sensorineural hearing loss, the vibration of bone from the BAHA is transmitted to the cochlea of the opposite ear

Figure 3 Bone-anchored hearing aid (BAHA) abutment implanted behind patient's right ear. The signal-processing device is connected to the abutment and translates sound into bone conduction for patients with conductive hearing loss or unilateral sensorineural hearing loss. Reprinted from http://www.headandneck.ucalgary.ca/postop_baha.htm, with permission.

allowing the perceived sensation of sound from the side of the head with the dead ear.

Figure 3 is a photograph of a patient implanted with a BAHA. The signal-processing device is connected to the abutment and translates sound into bone conduction.

3.25.2.2 Sensorineural Hearing Loss

As indicated earlier, sensorineural hearing losses involve the cochlea and/or auditory nerve (cochlear branch of VIII cranial nerve). Medical treatments for such losses include the administration of pharmacologic agents generally applied to stabilize hearing and, in some cases, reverse the progression of loss. Surgical treatments include cochlear implants, removal of space-occupying lesions, and surgeries designed to reduce fluid pressure within the endolymphatic system. The following section will describe the use of such treatments related to more common disorders of the inner ear/auditory nerve that cause/lead to sensorineural hearing loss.

3.25.2.2.1 Pharmacological treatments

A number of diseases have been identified in which pharmacological intervention potentially controls the progression of, or even reverses, sensorineural hearing loss. Some of the more common ones are described below.

3.25.2.2.1.(i) Menière's syndrome Menière's syndrome is the model disease when considering the treatment of inner ear disorders. First described by Prospère Menière in 1868, the disease consists of a triad of symptoms including attacks of vertigo, tinnitus, and fluctuating sensorineural hearing loss. The observation that sensorineural hearing loss can fluctuate is one of the earliest examples demonstrating that this type of loss can be reversible. Treatment of Menière's syndrome is mostly aimed at stabilizing the patient's balance. Two types of medications have emerged for the management of this often disabling disease. Diuretics are widely used based on the hypothesis that Menière's syndrome involves a disorder of inner ear fluid homeostasis and the observation that increased dietary salt is associated with more severe manifestation of the disease. Most clinicians would agree that dietary salt restriction and diuretics improve patients' symptoms and in many cases result in hearing returning to normal. Definitive clinical evidence has remained elusive, mainly due to the fluctuating nature of Menière's disease (Thirlwall, A. and Kundu, S., 2006). Beyond these measures a variety of other nonsurgical interventions have been used to help patients with Menière's syndrome, including positive pressure via hyperbaric treatment, or a hand-held pressure pump (termed the Meniett device) applied to the ear canal (Gates, G. A. and Green, J. D., 2002). Many of these approaches, although promising, have yet to demonstrate long-term effectiveness in the treatment of Menière's syndrome. Surgical interventions for the intractable form of the disease include endolymphatic sac decompression and intratympanic gentamicin treatment (Gates, G. A., 2005; Wittner, S., 2006). Menière's syndrome, despite being well described for over 150 years and estimated to affect about 50/100 000–75/100 000 adults (Pfaltz, C. R. and Matéfi, L., 1981), is emblematic of the problems encountered in the treatment of inner ear disease: (1) the pathophysiology of the disorder is not completely understood, (2) no absolutely reliable diagnostic modality exists, and (3) funding has not been committed to the execution of well-designed clinical trials.

3.25.2.2.1.(ii) Sudden sensorineural hearing loss Idiopathic sudden sensorineural hearing loss (ISSHL) occurs over a maximum of a 3-day period and can be associated with mild vertigo and tinnitus. The cause and pathogenesis of ISSHL remain unknown. Proposed theories of the pathogenesis of include viral cochleitis, vascular occlusion, and Reissner's membrane breaks (Mattox, D. E. and Simmons, F. B., 1977; Hughes, G. B. *et al.*, 1996). Several reports have described the postmortem pathologic findings in the temporal bones of cases of sudden deafness (Schuknecht, H. F. and Donovan, E. D., 1986). The majority of these cochleae showed atrophy of hair cells and supporting cells of the organ of Corti, with additional losses of the tectorial membrane, stria vascularis, and cochlear neuronal cells in varying combinations and severity. Recently, the hypothesis that ISSHL may be the result of pathologic activation of cellular stress pathways within the cochlea also was proposed (Merchant, S. N. *et al.*, 2005). The incidence of this disease in the US is estimated to range from 5/100 000 to 10/100 000.

Numerous drugs have been tested in an attempt to improve the outcome in patients presenting sudden sensory hearing loss. Among them, glucocorticoids are thought to influence the course of sensorineural hearing loss by decreasing inflammation resulting from viral infection or from altering immune response in the ear. Recent studies have demonstrated glucocorticoid receptors in the inner ear (Rarey, K. E. and Luttge, W. G., 1989), and glucocorticoids have been shown to influence the level of a variety of transcription factors that control inflammatory mediators. A study conducted by Wilson W. R. *et al.* (1980), who treated patients with ISSHL with steroids in a double-blind controlled trial, showed a significant improvement in hearing in steroid-treated individuals. Since then, steroid treatment for moderate-to-profound ISSHL has been the intervention of choice. Unfortunately, steroids can have significant side effects including gastric ulcers, mood changes, insomnia, and, in rare cases, avascular necrosis of joints. Intratympanic therapy for ISSHL also has been attempted (Chandrasekhar, S. S. *et al.*, 2000; Chandrasekhar, S. S., 2001; Kopke, R. D. *et al.*, 2001). Parnes L. S. *et al.* (1999) demonstrated a 54% improvement in ISSHL patients treated either with intratympanic methylprednisolone or dexamethasone. Other studies report some success with transtympanic steroid therapy for treatment of hearing loss in patients with various inner ear problems (Silverstein, H. *et al.*, 1996). Delivery of steroids to the middle ear and to the inner ear via the round window may achieve higher inner ear steroid concentrations while minimizing systemic side effects.

The partial or complete response rate to systemic steroid treatment for ISSHL is reported to range from 49 to 89% (Mattox, D. E. and Simmons, F. B.,

1977; Wilson, W. R. *et al.*, 1980; Hughes *et al.*, 1996). Several studies have demonstrated a much higher penetration of corticosteroids into inner ear fluids following topical application as compared with systemic administration presenting an opportunity to improve the treatment of this disease (Parnes, L. S. *et al.*, 1999; Chandrasekhar, S. S. *et al.*, 2000).

3.25.2.2.1.(iii) Autoimmune inner ear disease

There is considerable evidence to suggest that hearing and vestibular function can be influenced by autoimmune processes. In 1979, McCabe B. F. reported 18 cases of patients with progressive bilateral hearing loss responding to corticosteroids and/or cyclophosphamide. An autoimmune mechanism was suggested and he called this entity autoimmune sensorineural hearing loss (McCabe, B. F., 1979). A number of systemic autoimmune disorders include hearing loss and vertigo as part of their constellation of symptoms. Although classic evidence for a specific autoimmune etiology mediated by immune response directed solely at the inner ear is elusive, it appears that autoimmune damage can also exist as an entity confined to the labyrinth. Antigenic targets of autoimmunity within the labyrinth seem to be diverse. Partly because of this characteristic, the condition is difficult to diagnose (Ryan, A. F. *et al.*, 2001). Various tests can be used to detect several specific antibodies directed against antigens such as 58 kDa protein (Boulassel, M. R. *et al.*, 2001), 68 kDa protein (Ryan, A. F. *et al.*, 2001), or P0 protein (Cao, M. Y. *et al.*, 1996). Reactivity of patient sera against tissue sections of the inner ear has produced convincing labeling of sensorineural structures in some cases, but remains primarily a research tool (Soliman, A. M. and Zanetti, F., 1988). Diagnosis of autoimmune inner ear disease (AIED) is, therefore, based on the clinical findings and on the responsiveness to steroid therapy. Immune-mediated inner ear disease includes clinical conditions associated with unilateral or bilateral rapidly progressive sensorineural hearing loss. A systemic autoimmune disorder can be present in one-third of the cases (Welling, D. B., 1996). AIED has been reported in association with autoimmune diseases such as rheumatoid arthritis, systemic lupus erythematosus, Sjögren's syndrome, polyarthritis nodosa, relapsing polychondritis, Cogan's disease (Froelich, F. *et al.*, 1994), and Crohn's disease (Staecker, H. and Lefebvre, P. P., 2002; ten Cate, W. J. and Bachor, E., 2005).

Immunosuppressive drugs have been used to halt the progression of the hearing loss and in some cases were found to improve hearing. Early institution of high-dose oral prednisone daily for about 1 month is now widely used. Prednisone is then tapered slowly if a positive response to therapy is obtained (McCabe, B. F., 1979). Corticosteroids may have serious effects such as cataracts, gastrointestinal disturbances, and aseptic necrosis of the femoral head. Some patients develop a dependency on steroids with disease progression directly linked to the decrease of the steroid dosage. Recent progress in the development of novel treatments for autoimmune disease will hopefully lead to better treatments for AIED.

3.25.2.2.1.(iv) Ototoxicity and sound trauma

A wide variety of common medications have been found to be toxic to the auditory system. The most commonly seen in practice are aspirin, which reversibly inhibits outer hair cell motility; loop diuretics (Koegel, L., 1985), and aminoglycoside antibiotics, which are toxic to hair cells; and cisplatin, carboplatin, or any platinum-containing therapeutic, which are toxic to hair cells and auditory neurons (Moroso, M. J. and Blair, R. L., 1983; Tucci, D. L. and Rubel, E. W., 1990; Tsuji, K. *et al.*, 2000; Rauch, S. D., 2001; Shine, N. P. and Coates, H., 2005). Less commonly seen in clinical practice is ototoxicity due to vancomycin, quinine compounds, and industrial solvents such as styrene (Shine, N. P. and Coates, H., 2005; Lawton, B. W. *et al.*, 2006). Most efforts to treat ototoxicity have focused on dose limitation, careful monitoring, and avoiding combining ototoxins such as diuretics and aminoglycosides in clinical settings (Catlin, F. I., 1985; Stavroulaki, P. *et al.*, 2001; Shine, N. P. and Coates, H., 2005). Recently a better understanding of the molecular pathways that are induced in ototoxicity have led to a variety of strategies that may become useful for preventing ototoxicity (Chiodo, A. A. and Alberti, P. W., 1994; Lopez, I. *et al.*, 1999; Rybak, L. P. *et al.*, 1999; Schacht, J., 1999; Yagi, M. *et al.*, 1999). A recent human clinical trial has also demonstrated the ability to prevent aminoglycoside ototoxicity using pretreatment with aspirin (Sha, S. H. *et al.*, 2006). This finding is somewhat surprising in that aspirin, as described above, also can cause sensorineural hearing loss (although, aspirin-induced loss usually is reversible upon cessation of the drug). Postulations on why aspirin may have a protective effect on hearing include its role in reducing oxidative stress and/or increasing vascular flow to the cochlea.

Sound trauma (noise-induced hearing loss) is another very common cause of sensorineural hearing

loss that is largely preventable through the use of hearing protection and monitoring of individuals routinely exposed to high sound levels, be it through the workplace or recreational/leisure activities (van der Laan, F. L., 2001; Davis, R. R. *et al.*, 2003; Le Prell, C. G. *et al.*, 2003; Miller, K., 2004). Application of molecular strategies to prevent sound trauma to the inner ear are being actively explored (Sohmer, H., 1997; Henderson, D. *et al.*, 1999; Waters, C., 1999; Kopke, R. *et al.*, 2005; Henderson, D. *et al.*, 2006).

3.25.3 Surgical Treatments

3.25.3.1 Cochlear Implants

Despite the progress made in understanding and treating sensorineural hearing loss, rehabilitation of hearing with amplification is the primary treatment for most patients with this general condition. The effectiveness of amplification is dependant on the patient having a functional sound transduction mechanism. Without hair cells, an endocochlear potential, and a reasonable complement of auditory neurons, amplification using hearing aids is not possible. Cochlear implantation has enabled patients who do not have the capacity of sound transduction to hear by bypassing the function of hair cells and directly stimulating surviving auditory neurons. This process is accomplished by combining an implanted electrode array that is driven by an external speech processor (Merzenich, M. M. *et al.*, 1980; Clark, G. M. and Tong, Y. C., 1981; Harrison, R. V., 1987; Schloss, M. D., 1987; Nadol, J. B. and Eddington, D. K., 1988). Figure 4 illustrates the components of an adult cochlear implant. Figure 5 is a photograph of an actual device.

Candidates for cochlear implantation range from patients with poor speech discrimination and relatively normal hearing thresholds to patients with profound sensorineural hearing loss. Evaluation of patients is divided into adult and pediatric populations (Merzenich, M. M. *et al.*, 1980; Gantz, B. J., 1989; Kveton, J. and Balkany, T. J., 1991; Tyler, R. S. and Lowder, M. W., 1992; Souliere, C. R. *et al.*, 1994). For adult patients key criteria include prior presence of hearing and development of speech. Patients who never possessed hearing tend to have poor outcomes and results in noncompliance with the device. Outcomes in adults vary from sound awareness to open set speech recognition with duration of deafness being a predictor of successful implantation. Implantation in infants is a rapidly evolving field. Evidence is mounting that, for children who are born profoundly deaf, earlier implantation results in better speech/language development. Age of implantation is becoming younger as hearing screening and genetic testing combine to give a definitive diagnosis of hearing loss (Merzenich, M. M. *et al.*, 1980; Cullen, R. D.

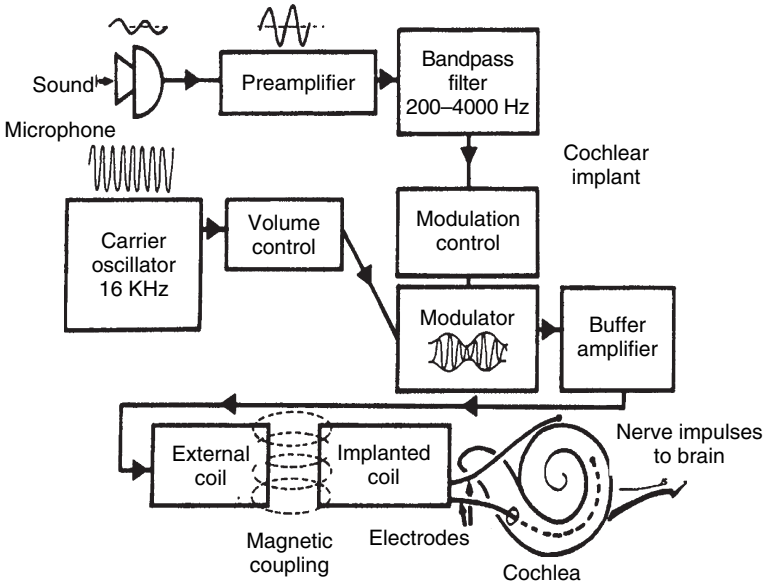

Figure 4 Basic components of an adult cochlear implant. From Waltzman, S. B. and Shapiro, W. H. Cochlear implants in adults. In: M. Valente, H. Hossford-Dunn, and R. Roesser (*eds.*) Audiology: Treatment. Thieme Medical Publishing; 2000: 537–546. Reprinted by permission.

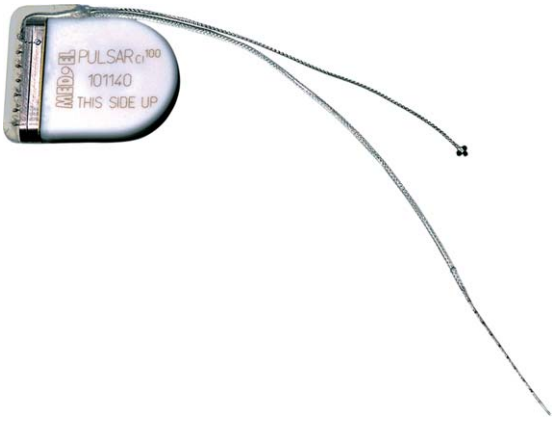

Figure 5 Adult cochlear implant device.

et al., 2004; Horn, D. L. *et al.*, 2005; Fitzpatrick, E. *et al.*, 2006; Wiley, S. *et al.*, 2006).

Evolution of cochlear implant technology is occurring on several fronts. The devices are becoming smaller with a larger number of electrodes and are capable of progressively higher stimulation rates. In parallel, new software is being developed that takes advantage of improved hardware and features reduced channel interference and the ability to use advanced speech processing. Bilateral implantation studies have been performed in both adults and children and have demonstrated improved sound localization and hearing in background noise (Das, S. and Buchman, C. A., 2005).

For patients who have agenesis of the cochlear nerve, trauma with bilateral transection of the cochlear nerve, or neurofibromatosis type 2, implantation with standard cochlear implants is not possible. For these patients auditory brainstem implants can provide some hearing rehabilitation (Cervera-Paz, F. J. and Manrique, M. J., 2005; Ramsden, R. *et al.*, 2005).

3.25.3.2 Endolymphatic Sac Decompression

The endolymphatic sac is a blind pouch, connected to the saccule and utricle of the membranous labyrinth of the vestibular system via the endolymphatic duct. In patients with sensorineural hearing loss related to Menière's disease, elevated pressure within the endolymphatic system has been postulated to contribute to both vestibular symptoms of this disease and hearing loss (Ghossaini, S. N. and Wazen, J. J., 2006). In select patients refractory to medical management, surgical decompression of the endolymphatic sac or placement of a shunt to divert fluid can reduce endolymphatic pressures and help stabilize sensorineural hearing loss (Shah, D. K. and Kartush, J. M., 1997). Since its initial description in the 1920s, an active debate within the literature continues regarding the effectiveness (or lack thereof) of endolymphatic sac surgery for the treatment of Menière's disease.

3.25.3.3 Treatment for Acoustic Neuromas

Acoustic neuromas are benign tumors of the auditory nerve, with the majority affecting vestibular function. Figure 6 displays the radiographic image of a patient with a left, cerebellopontine angle acoustic neuroma.

Data suggest that the annual incidence of acoustic neuromas in the general population is 1/100 000 (Tos, M. and Thomsem, J., 1984), although autopsy studies indicate that asymptomatic tumors have a much higher prevalence (Leonard, J. R. and Talbot, M. L., 1970). As these tumors grow, clinical manifestations occur due to compression of surrounding structures due to the limited space of the cerebellopontine angle where the auditory nerve traverses.

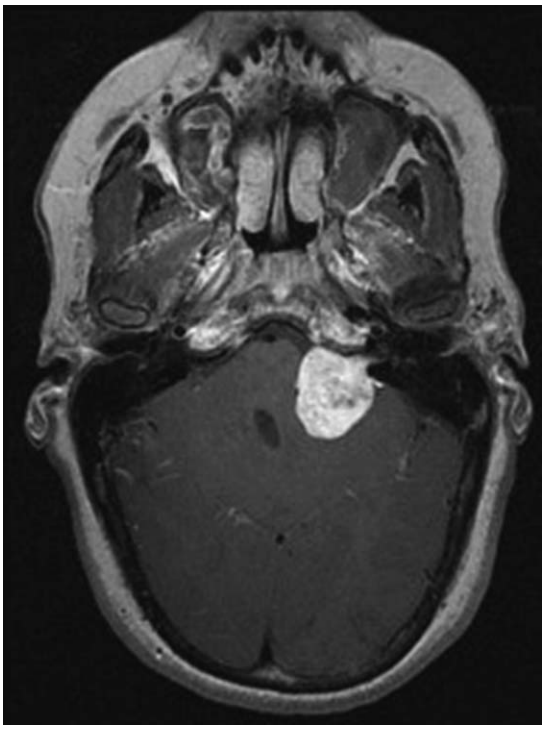

Figure 6 Acoustic neuroma of the left cerebellopontine angle. Notice the tail of the tumor entering the internal auditory canal. This patient had surgical removal of the tumor with a behind the ear approach.

The majority of acoustic neuromas occur as spontaneous mutations, but 5% are associated with neurofibromatosis type 2. In these individuals, acoustic neuromas develop at an earlier age, are more aggressive, and are bilateral. Unilateral hearing loss is observed in more than 85% of affected individuals (Selesnick, S. H. and Jackler, R. K., 1993). Tinnitus is the second most common symptom, affecting over 50% of afflicted individuals, and usually is described as hissing, ringing, or buzzing.

The gold standard for diagnosis of acoustic neuromas is magnetic resonance imaging (MRI) with gadolinium contrast. The auditory brainstem response also can also be used for diagnosis, often as a precursor to MRI. Treatment options are necessarily limited for acoustic neuromas and include surgical removal or stereotactic gamma irradiation. If the tumor is small, slow growing, and accompanied by minimal symptoms, surgery/irradiation may be withheld in favor of careful monitoring over time via imaging and electrophysiological tests, and patient feedback.

3.25.4 Nonmedical/Nonsurgical Treatments

Approximately 95% of adult hearing loss cases cannot be treated medically/surgically. In cases when medical management cannot reduce the hearing loss, hearing aids are the primary treatment. Most people become a candidate for hearing aid use when communication is negatively affected by their hearing loss. By pursuing amplification the patient hopes to gain improved speech understanding, a comfortable physical fit, and good sound quality. It is important to determine patient expectations and provide counseling on benefits and limitations of hearing aids. Hearing-impaired individuals have unique self-perceived communication needs that must be identified prior to hearing aid selection. Several self-assessment instruments such as The Abbreviated Profile of Hearing Aid Benefit (APHAB; Cox, R. and Alexander, G., 1995) and the Client Oriented Scale of Improvement (COSI; Dillon, H. *et al.*, 1997) are available to help the audiologist determine these communication needs. Although hearing aid use is beginning to increase, Kochkin S. (1994) reported that only 20% of those who needed hearing aids actually purchased them. Numerous factors contribute to this poor market penetration, including denial of communication difficulties and stigma related to hearing aid use. In general, however, hearing aid use has been shown to improve social, emotional, and communication function, as well as improve the user's self-concept and cognitive function, and decrease depression (Harless, E. and McConnnell, F., 1982; Mulrow, C. D. *et al.*, 1990; Cox, R. *et al.*, 1991; Mulrow, C. D. *et al.*, 1992).

3.25.4.1 Hearing Aid Types

There are two fundamental types of hearing aids, analog and digital. The basic components of an analog hearing aid comprise a microphone, amplifier, and receiver. The microphone picks up the acoustic signal from the environment and converts it to an electrical signal. The electrical signal is then passed through an analog amplifier before being sent to the receiver for reconversion to an acoustic signal. A volume control allows the user to adjust the loudness of the hearing aid and a telecoil option enhances telephone communication. Since 2000, there has been a dramatic increase in the availability of digital hearing aids, which employ digital technology to manipulate the input signal. The current generation of digital hearing aids provides variable gain at selective frequencies, compression of high-level signals, and attenuation of background noise through adaptive filtering, directional microphones (DMs), and multiple programs.

3.25.4.2 Hearing Aid Styles

Hearing aid components can be packaged into a variety of hearing aid styles as illustrated in Figure 7. A brief description of these styles is presented below.

3.25.4.2.1 Completely-in-the-canal

The completely-in-the-canal (CIC) is the smallest style of hearing aid made and is cosmetically appealing since it is almost invisible in the ear. All the components are housed in a small case that fits deep into the ear canal. This deep insertion allows use of the ear's natural sound-modifying resonance, and offers easy telephone usage. Less gain is needed, particularly for the higher frequencies, because the decrease in ear canal volume allows for a higher sound pressure at the tympanic membrane. Users typically report less wind noise with CICs because the microphone is protected by the ear canal and tragus. Also, users report less occlusion effect (quality of the user's voice; Killion, M. *et al.*, 1988). However,

Figure 7 Various hearing aid styles. CIC, completely-in-the-canal; ITC, in-the-canal; ITE, in-the-ear; BTE, behind-the-ear.

advanced digital circuits often cannot be incorporated into a CIC due to its small size and there is a slightly higher repair rate due to cerumen build up. CICs are custom made for each ear and are restricted to persons with ear canals large enough to accommodate the insertion depth. Also, the CIC style uses a very small battery that requires good manual dexterity for insertion. This type of hearing aid is suitable for persons with mild-to-moderate hearing loss.

3.25.4.2.2 In-the-canal and in-the-ear

These two custom-made hearing aids (in-the-canal (ITC) and in-the-ear (ITE)) fit completely in the external canal and protrude into the concha of the external ear. The ITC is smaller and fills about half of the concha. Because of their larger size in comparison to CIC aids, ITCs can accommodate recent technological advancements such as DM and telephone options, if the patient's ear canal is large enough to permit housing of these features. ITCs can also incorporate a volume control for the user and are more cosmetically appealing than hearing aids worn more external to the EAC. ITCs are appropriate for mild-to-moderately severe losses. ITE aids are larger and fill the entire concha area. Since the 1980s, ITC/ITE hearing aids have been the most popular styles of hearing aids in the USA, being chosen by approximately 90% of new users (Mueller, H. G. and Budinger, A. C., 1990). ITE aids are less popular in Europe where they account for approximately 40% of new hearing aids issued (Vonlanthen, A., 2000). ITE aids are easier to handle because of their larger size and typically have better battery life than smaller hearing aids and are capable of housing all the advanced circuits of hearing aid technology. ITEs are appropriate for mild-to-severe hearing loss.

3.25.4.2.3 Behind-the-ear

With behind-the-ear (BTE) hearing aids, the components are housed in a case that fits behind the ear. This type of hearing aid is connected to a custom-made earmold that directs the sound into the EAC. Because of its larger size and physical separation of the microphone and receiver, higher gain and output can be achieved without acoustic feedback. BTE hearing aids are the most flexible and durable style of hearing aid, which makes them especially appropriate for young children. BTE hearing aids can provide more amplification than smaller devices due to the powerful amplifier and the larger battery. One of the biggest advantages, however, is the ability to couple the BTE hearing aid to assistive technology, which will be discussed later in this chapter. This hearing aid style is the most powerful of the ear level hearing aids and is appropriate for mild-to-profound hearing losses. BTEs are gaining popularity in the USA as miniaturization has made them smaller and more cosmetically appealing to consumers. In fact, recent market trends indicate approximately 40% of new users are now selecting BTE aids.

3.25.4.2.4 Mini-behind-the-ear

The newest hearing aid style on the market is the mini-BTE. It is not as strong as a traditional BTE hearing aid and is fitted with an open noncustomized ear piece. These hearing aids are optimum for mild-to-severe high-frequency hearing loss and are cosmetically appealing because they are nearly invisible. Since the ear piece is noncustom these hearing aids can be fitted on the same day as the hearing evaluation. They are easy to insert and also reduce the occlusion effect for persons with normal low-frequency hearing. Mini-BTEs are not compatible with assistive technology. However, they can incorporate other modern technologies, but rarely have a volume control.

Hearing aid industry studies have documented that approximately 80% of people who need hearing aids do not purchase them. While there are numerous factors that contribute to the stigma of wearing a hearing aid, cosmetics issues appear to be a primary reason (Kochkin, S., 1994). Cosmetic aspects of hearing aid use include not only the concern

about wearing a device that calls attention to a sensory deficit, but that this deficit often is associated with growing older. Recently, Johnson C. E. *et al.* (2005) found that observers rated the CIC as having the least visibility and the mini-BTE and mini-ITC the next most invisible. Abrams H. *et al.* (2004) found that new hearing aid users are willing to pay more for CICs than other styles. These findings are important as hearing aid dispensers counsel potential reluctant hearing aid wearers. However, the dispenser must balance the cosmetic concerns with the needs of the hearing-impaired individual.

3.25.4.3 Binaural versus Monaural Amplification

In most cases, binaural amplification has significant advantages over monaural amplification. Two primary advantages are improvement in localization of sound and speech understanding in noise (Ricketts, T. A., 2005). Another advantage is loudness summation, which can provide a 3 dB improvement in thresholds. Binaural amplification helps eliminate the head shadow effect by allowing sound to be received on both sides of the head. With only one hearing aid, sounds from the unaided side, particularly high frequencies, can be attenuated by as much as 15 dB. In addition, binaural amplification provides a signal-to-noise improvement of approximately 3 dB, which can result in a 30–40% improvement in speech understanding (Mueller, H. G. and Hawkins, D. B., 1990). There is sufficient evidence to conclude that individuals with bilateral hearing loss should be fitted with two hearing aids (Valente, M., 1982a; 1982b).

3.25.4.4 Recent Technological Advancements in Hearing Aids

Miniaturizations with enhanced signal processing and improved microphone technology have been at the forefront of recent hearing aid advancements. Hearing aids now have multiple memories, microphones and channels, expansion and noise reduction circuits, feedback cancellation, and digital signal processing (DSP). Most modern hearing aids have computerized programming capabilities, which allow the audiologist to adjust frequency, gain, and output characteristics. The biggest challenges facing hearing aid users today is the ability to understand speech in the presence of background noise. A great deal of research and development has focused on resolving this problem. Primarily, two technologies have been used to enhance speech understanding in noise: DMs, and DSP.

3.25.4.4.1 Microphone technology

Until the mid-1990s most hearing aids incorporated omni-DMs, which consist of a single microphone that transduces sound uniformly from all directions. Directionality with regard to hearing aids means the hearing aid treats sounds differently depending on the location of the sound source. Conventionally directional hearing aids used a single microphone with two ports and acoustic delay. Newer directional hearing aids use two microphones (two omni-directional or a directional plus omni-directional) with electronic delay and subtraction. Understanding the benefits of current hearing aid DM technology requires familiarity with microphone polar plots, since newer hearing aids support multiple directional responses. Varying by microphone design and frequency, polar plots simply provide a graphical display of microphone output for different incident sound directions. Figure 8 displays polar plots for the types of microphones described below.

Omni-directional. The omni-DM treats all directions as equals. There is no differential attenuation of sound from any direction. However, even the use of omni-DMs can yield some directional characteristics such as a decrease in ipsilateral and contralateral sounds because of the shadow of the head, and pinna effects (Dillion, H., 2001).

Cardioid. Cardioid microphones are sometimes described as heart-shaped, which is the type of directionality pattern this microphone possesses. Sound is picked up mostly from the front and to a lesser extent from the sides. As shown in Figure 8, maximum rejection (null) is at the rear of the microphone. The maximum difference in sound reception is between the front and the back of the microphones. This response pattern is ideal if speech originates from the front and noise from the back. However, this situation rarely happens in the real world as noise is typically diffuse and rarely comes from one direction.

Supercardioid. Supercardioid microphones have a response pattern similar to cardioid microphones, but do allow some reception of sound from the rear. Note from Figure 8 that there are two nulls (one on each side) of maximum sound rejection. This response pattern has a higher directivity index (DI) than the cardioid pattern.

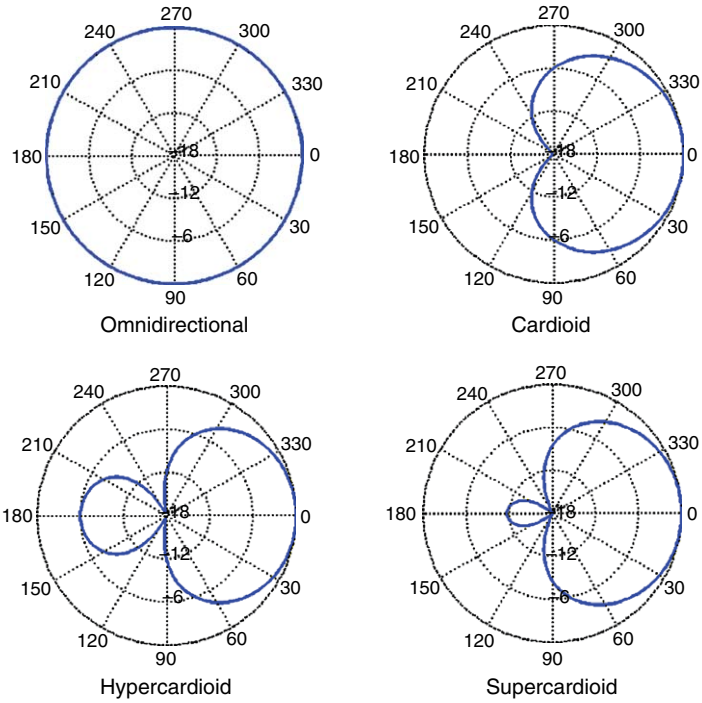

Figure 8 Polar plots for different types of hearing aid microphones. The contours provide a graphical display of microphone output from different directions.

Hypercardioid. Hypercardioid microphones have a similar response pattern to supercardioid microphones but are more responsive to sounds arriving at 180°. As shown in Figure 8, there are two nulls, with maximal attenuation at 130° and 230°. The hypercardioid pattern has a higher DI than cardioid and supercardioid patterns and theoretically provides more directional benefit.

3.25.4.4.2 Directional microphone hearing aid technology

DM hearing aid technology is an exciting advancement in modern hearing aids due to its potential for improving speech understanding in noise. It is well documented that use of DMs is able to increase the signal-to-noise ratio (SNR), therefore improving speech understanding in noise (Valente, M. *et al.*, 1995; Ricketts, T. A. and Mueller, H. G., 2000; Ricketts, T. A. and Dittberner, A. B., 2002). The improvement of the SNR varies, depending on environmental reverberation, the noise source, and distance from the listener (Hawkins, D. B. and Yacullo, W. S., 1984; Novick, M. *et al.*, 2001). The amount of microphone directionality is quantified by measuring the DI, which compares the reception of sounds originating from the front of the hearing aid to sounds originating from all other locations. The DI is expressed in decibel (dB) levels and the higher the DI the more directional the response of the hearing aid. An omni-DM would be expected to have a DI of 0 dB, while a cardioid or hypercardioid microphone might have a DI of 5–6 dB. Theoretically, speech understanding in noise increases as DI increases.

Directionality can be fixed at a certain point in space or made adaptive, so that the response pattern changes depending on the location of the sound source. No directionality benefit has been demonstrated between fixed and adaptive DMs in a diffuse noise environment (Bentler, R. A. *et al.*, 2004). However, speech understanding in noise was significantly worse for the omni-DM condition, when compared to all the DM conditions. Directionality can be manually controlled by the hearing aid wearer with a push button on the hearing aid, or automatically with the hearing aid deciding when to switch from omni- to directional mode. Automatic features are widely used in current hearing aid technology. However, Walden B. E. *et al.* (2004) and Palmer C. *et al.* (2006) have indicated that automatic directionality may not always be preferred by the hearing aid users. One disadvantage of

automatic features is the tendency to switch to directional when the overall intensity of the input level reaches a certain value, even if speech is not present. Also, automatic options sometimes switch into directional mode even when speech is coming from the back, which puts the listener at a significant disadvantage for understanding speech.

In general, DMs are used in modern hearing aids with impressive benefits and few limitations. However, if the noise source is in front of the listener, the DM will be of no benefit. Some DM users have reported higher levels of internal noise that may be audible in quiet environments, and more sensitivity to wind noise. However, these problems can usually be eliminated by using the expansion feature of the aid or switching the aid to omni-directional mode. The limitations of microphone directionality primarily relate to the environmental listening conditions, and the number of microphone ports, which is limited by the size of the hearing aid. Although there are some isolated limitations of DMs, this technology is the only one that is proven to provide improved speech understanding in noise.

3.25.4.4.3 Digital signal processing

With DSP hearing aids the acoustic analog signal is converted into discrete positive and negative electrical signals (i.e., into a digital form). Various signal-processing algorithms are incorporated into the microprocessor, and multiple algorithms can be incorporated into a single hearing aid. One algorithm might control the frequency response, one might enhance speech in noise, and yet another might control the loudness output of the hearing aid. Sophisticated DSP algorithms provide increased alternatives and enhanced options for hearing aid users.

The advantages of hearing aid DSP technology lie in its expanded capacity for processing the signal. DSP technology allows the hearing aid to adapt to the individual listening needs of the hearing aid user. For example, adaptive directional systems can change the response pattern of the microphone to improve the SNR and maximize speech understanding in noise. Also, DSP algorithms allow automatic switching between omni- and DM modes, and multiband directionality. Adaptive feedback management can analyze the feedback path to minimize or eliminate feedback without decreasing gain or output.

DSP technology also has limitations. Despite advancements in hearing aid DSP, laboratory studies have yet to demonstrate improved speech understanding in noise as compared to analog hearing aids (Walden, B. E. *et al.*, 2004; Alcantara, J. *et al.*, 2003). In addition, DSP technology is expensive and cost-prohibitive for many potential hearing aid candidates. No technology, including DSP, can restore the exquisite processing of a normal auditory system. This basic truth is an important consideration when counseling patients regarding the benefits and limitations of DSP hearing (and hearing aids in general for that matter). Without the ability to change the pathophysiology or neurology of the impaired cochlea or auditory nerve there always will be limits to hearing aid benefit. If a hearing-impaired individual has poor speech understanding abilities, they will receive limited benefit from even the most sophisticated DSP or analog hearing aid, as these devices cannot improve the distortion of speech secondary to ear pathologies.

In the early stages of digital hearing aid use consumers had high expectations. Kochkin S. (2002) reported that 95% of hearing aid users would like improved speech intelligibility in background noise; 88% wanted better sound quality; 83% wanted to be able to hear soft sounds better; and 81% wanted greater comfort for loud sounds. More recently, Kochkin S. (2005) has reported significant improvement in hearing aid customer satisfaction, with mostly digital hearing aids. For hearing instruments 0–5 years old, customer satisfaction was 71% while satisfaction with 1-year-old instruments was 78%. According to Kochkin S. this satisfaction rating placed hearing aids in the top third of all products and services measured in the USA. Eighty five per cent of users were satisfied with the ability of their hearing aids to improve their hearing, which is interpreted to mean they were receiving tremendous benefit. Hearing aid users received the most benefit (90%) for one-on-one conversations and the least benefit for cell phone use (59%). Six out of 10 hearing aid wearers surveyed were satisfied with their instrument in 80% of the listening situations measured. Hearing aid benefit was lower when the user had severe-to-profound hearing loss. In general, digital hearing aids provided significantly higher overall satisfaction, benefit, sound quality, feedback reduction, and improved performance in noisy environments. There have been significant enhancements in quality-of-life issues with DSP hearing aids. Ninety-three per cent of the hearing aid wearers reported more effective communication and enhanced social life. In addition, seven out of 10 hearing aid wearers reported improved mental/cognitive abilities and physical health. Improved customer

satisfaction and hearing aid benefit has resulted in an increase in the utilization of DSP, with 90% of hearing aids dispensed in 2005 being digital. In 1999, when only 5% of the hearing aids dispensed were digital, customer satisfaction was only 59% (Kochkin, S., 1994). Although these surveys are based primarily on perception, they do indicate an obvious preference for digital technology by hearing users; however, comparative studies between analog and digital hearing aid performance fail to demonstrate superiority of digital instruments. In addition, the specific features that tend to make digital technology more preferred by hearing aid users have not been well defined and tend to be very subjective.

3.25.4.5 Hearing Aid Fitting Verification

As hearing aid technology becomes more complicated, appropriate fitting and programming of the aids also has become more complex. Much of the success of the hearing aid user depends on the professional expertise of the audiologist or hearing aid dispenser. It has become increasingly important to verify that the hearing aid is actually performing according to the manufacturer's specifications and is meeting the needs and expectations of the patient. When a custom hearing aid is ordered, the manufacturer will pre-program the hearing aid based on the users hearing loss, an average ear canal resonance, and one of several commercially available fitting algorithms. Some audiologists question the need for verifying the manufacturer's pre-programming with digital instruments, assuming the manufacturer's estimate will accurately predict the appropriate output and gain needs of individual hearing aid users. However, several studies have noted dramatic differences between manufacturer's estimates and the actual gain measured in the patient's ear canal with real-ear measurements (Hawkins, D. B. and Cook, J. A., 2003; Aarts, N. L. and Caffee, C. S., 2005). In fact, Aarts N. and Caffee C. S. (2005) reported that the values predicted by the manufacturer were inaccurate for almost all the subjects studied. Because of these discrepancies it is incumbent on the audiologist to validate hearing aid function routinely. This task can be accomplished by several measures.

The most effective (gold standard) measurement technique for validating hearing aid function is real ear probe microphone measurement, which requires no response from the patient. A small silicone tube is placed in the patient's ear canal, and a signal is presented to a monitoring microphone located near the ear. Sound pressure level (SPL) ear canal measurements are made with and without the hearing aid in place. These SPLs can then be used in a hearing aid fitting program that provides target output for different input levels. In addition, real ear measures can be used to measure effectiveness of DMs and the smoothness of the frequency response of the hearing aid. Other verification measures for hearing aid performance include functional gain measurements and assessment of aided and unaided speech understanding in quiet and in the presence of background noise.

In addition to verification of hearing aid performance, self-reported outcome measures are helpful to ensure that the hearing aid is meeting the needs and expectations of the patient. Outcomes are simply defined as measurable differences resulting from treatment (Frattali, C. M., 1998). Outcome measures fall into two general categories: self-report from the patient such as the previously mentioned APHAB, and objective measurement of performance such as tests of speech in noise and real ear measurements. Self-reported outcomes provide a complement to real ear measures because they reflect how the user performs with the hearing aid and its perceived benefit. These measures allow the audiologist to determine the effectiveness of hearing aid intervention. In addition, they help the consumer determine efficacy of treatment, provide objective evidence for third party payment, and assess quality-of-life issues (Saunders, G. H. and Jutai, J. W., 2004). The audiological evaluation determines the type and degree of hearing impairment, but the disability (activity limitation) or handicap (participation restriction) of the hearing loss on the individual can only be assessed with self-reported measures (World Health Organization, 2001). A combination of real ear measures and self-reported outcome measures help assure that individual amplification goals are met.

3.25.4.6 Assistive Listening Devices

Even with the best hearing aid technology, some hard of hearing individuals have continued communication or safety needs because of the nature of their hearing loss and/or daily communication demands. Assistive listening devices (ALDs) help to meet these needs. Compton C. L. (2000) suggests hearing-impaired individuals have four basic communication needs that ALDs should address: face-to-face communication, enjoyment of broadcast or other media, telephone communication, and alerting devices.

Frequency-modulated (FM) systems are a type of ALD used to enhance face-to-face communication, which incorporate a microphone transmitter and a receiver worn by the hard of hearing individual. The primary advantage of this system is improved SNR. FM systems can be coupled to a BTE hearing aid or used independently. Because the microphone of the transmitter is located in close proximity to the speaker's mouth, the FM system minimizes the effects of room reverberation, distance, and noise on speech understanding (Crandell, C. *et al.*, 1995).

Other ALD devices such as infrared and induction loop systems can be used to enhance reception of television, movie, and other media. Numerous ALDs are available to assist with telephone communication. Examples include amplified telephones with volume controls and text telephones which allow the user to read the incoming conversation on an LCD screen and respond by typing or speaking. Various alerting devices help hard of hearing individuals hear environmental sounds necessary for safety and daily living such as smoke alarms, telephones, and alarm clocks. These devices also require a microphone transmitter to send a message to a receiver. The receiver can be attached to loud auditory signals, visual stimuli such as a bright flashing light, or vibrotactile stimuli such as a bed shaker.

3.25.4.7 Aural Rehabilitation

Aural rehabilitation (AR) emerged as a result of World War II for the purpose of minimizing or lessening the negative effects of hearing loss on communication, and continues to be an important supplement to hearing aid and cochlear implant use. Initially AR emphasis was on use of visual cues and auditory training. However, AR has advanced to new levels, with individualized training programs. An adult AR program might include speech reading, lip-reading, assertiveness training, communication strategies training, and counseling regarding psychosocial and emotional aspects of hearing loss. For children, an AR program might additionally include auditory training, speech-language therapy, and academic assessment. Recently computerized AR programs have been developed, which allow the hearing-impaired individual and their families to implement the program at home.

3.25.5 Summary

Although significant progress has been made in the treatment and management of hearing loss, many hurdles still remain in the quest to improve the hearing of individuals who suffer from this condition. This chapter described more common causes for hearing loss and their current treatments. As can be seen from this material, most conductive losses respond well to medical and/or surgical treatment. Unfortunately, it remains the case that there are few if any real cures for the majority of sensorineural disorders. As we have described, medical and surgical treatments can sometimes halt and even reverse the progression of sensorineural losses. In addition, coping with hearing loss has been made considerably easier by great strides in technology, such as cochlear implants, hearing aids, and other ALDs as well as behavioral modification strategies. Despite these advances, the secrets to revitalizing human cochlear hair cells or auditory nerve fibers that have been destroyed by genetic aberrations, disease, trauma, ototoxic chemicals, or aging continue to elude us. On the plus side, cochlear hair cell regeneration represents one of the hottest areas of current research in the hearing sciences. The emerging technology of stem-cell therapy is yet another tool that may have a role in future the treatment of hearing loss. The notion of inserting stem cells into the inner ear that eventually develop into functional sensory hair cells is attracting considerable scientific interest throughout the world.

3.26.1 Introduction

When the concept of cochlear implants was initially proposed it was dismissed as absurd – it was thought that an artificial device replacing the complex function of the inner ear was impossible. Replacing the functionality of 30 000 nerve fibers with a small number of electrodes did not seem like a viable prosthesis. Auditory researchers were so focused on the cochlea and its complexity, that they overlooked a highly important part of hearing – the brain. Now it is clear that to understand hearing fully and to design the next generation of prosthetic devices we must have better understanding of the ear–brain system. Some aspects of hearing do not require the intricate complexities of cochlear physiological responses, while other auditory tasks rely critically on specialized details of cochlear processing. In this chapter we will review basic design and signal processing of cochlear implants, basic perceptual capabilities, and implications for future research.

3.26.2 Cochlear Implants

Most types of deafness are caused by loss or malfunction of the sensory hair cells in the inner ear. The inner row of hair cells normally converts the vibrational energy of sound into neurotransmitter release, which activates auditory neurons. When the inner hair cells are damaged, sound-induced vibration in the cochlea is not converted to nerve impulses. Cochlear implants are prosthetic devices that are intended to bypass the damaged inner hair cells and stimulate the auditory neurons directly with small electrical pulses. Multiple electrodes are placed through the round window of the cochlea and into the scala tympani. Present cochlear implants have 12–22 electrodes placed along the tonotopic dimension of the cochlea. Insertion depth of the electrodes varies across the device designs, and also depends on the anatomical pathology of the individual patient, but typically extend 20–30 mm inside the round window. Figure 1 shows a typical cochlear implant. The electrode array is inserted through a cochleostomy and sealed at the round window. The wires exit through the surgical opening and connect to the internal electronics package, which is fixed to the skull near the mastoid. The implanted electronics package contains an antenna-receiver that receives the radio signal transmitted across the skin and hermetically sealed circuitry that decodes the signal and routes the appropriate electrical stimulating pulse to the appropriate electrodes. Stimulating pulses are typically biphasic current pulses. Some devices contain multiple current sources and so can stimulate multiple electrodes simultaneously while others contain a single current source that is rapidly switched across electrodes. Modern devices have microprocessor circuitry that can contain simple programs to implement complex stimulation algorithms, and most have reverse telemetry capabilities – sending electrical potentials from the electrodes out across the skin to external devices. These components allow recording of evoked potentials and electrical fields from electrodes inside the cochlea.

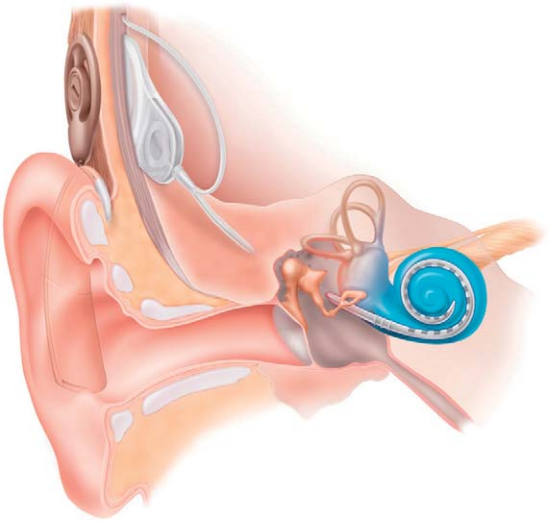

Figure 1 A diagram of a cochlear implant, which is composed of external and internal portions. The external portion contains a microphone and signal processor (shown behind the ear) and a transmission coil (located above the ear) that sends the coded signal across the skin to the implanted portion. The implanted portion of the implant contains a pick-up antenna coil, a receiver-stimulator which decodes the signal received from the external transmitter, and the intracochlear electrode, which is inserted into the cochlea. Reproduced with kind permission of Cochlear Ltd.

The external portion of a cochlear implant is worn on a belt or behind the ear, much like a hearing aid. The external portion contains a microphone, a signal processor, and a transmitter coil that sends the coded signals to the implanted portion of the implant.

3.26.3 Cochlear Implant Psychophysics

Cochlear implants produce auditory sensation by electrically activating neurons near the stimulating electrodes in the scala tympani. The patterns of activation of those nerves are quite different to those produced by acoustic stimulation of a normal cochlea. In electrical stimulation, the activated region is essentially symmetrical around the stimulating electrode, complicated by the spiral geometry of the cochlea, and the pattern spreads equally to the apex and base as the current level is increased (van den Honert, C. and Stypulkowski, P. H., 1984; 1987a). In contrast, acoustic stimulation produces a localized pattern of activation at low stimulus levels and the pattern spreads asymmetrically as level is increased. Electrical activation spreads linearly with stimulating current while acoustic activation is strongly compressed. In addition, the normal cochlea produces a high rate of spontaneous activity in the auditory nerve, and the response becomes strongly (but stochastically) phase locked to periodic stimuli as the sound level is increased. Electrical stimulation produces highly abnormal phase-locking even at levels just above threshold (van den Honert, C. and Stypulkowski, P. H., 1987b). At stimulation rates below 300 Hz, the phase-locking produced by electrical stimulation is much stronger in both time and place than for acoustic stimulation; neurons fire on every stimulus cycle. Neurons fire in a more stochastic temporal pattern when electrical pulses are presented at rates of 4 kHz or higher, due to the probabilistic nature of recovery from refractoriness (Wilson, B. S. *et al.*, 1997).

3.26.3.1 Amplitude Coding

As electrical stimulation current is raised above threshold the loudness increases. The dynamic range of electrical hearing, defined as the range between threshold and the loudness level that is tolerably but not uncomfortably loud, is typically 10–20 dB. Since the acoustic dynamic range is 120 dB there is a need for compression mapping from acoustic to electric amplitude in a cochlear implant. This is not surprising because electrical stimulation bypasses the normally compressive mechanical function of the cochlea, which is principally produced by outer hair cells. Studies of loudness in cochlear implants and auditory brainstem implants indicate that loudness for an electric stimulus increases as an exponential function of the stimulating current (Zeng, F. G. and Shannon, R. V., 1994; Zeng, F. G. *et al.*, 1998; Zeng, F. G. and Shannon, R. V., 1999). Within the electrically produced dynamic range, people with cochlear implants can only differentiate 20–40 steps of intensity, compared to more than 200 discriminable intensity steps for acoustic hearing (Nelson, D. A. *et al.*, 1996). Studies have shown that only eight steps in amplitude are adequate for speech recognition (Loizou, P. C. *et al.*, 2000), but more resolution may help in difficult listening situations.

3.26.3.2 Temporal Coding

Although electrical stimulation produces an abnormal temporal response in the auditory nerve,

temporal perceptual responses are relatively similar to those of acoustic hearing. Psychophysical measures of gap detection, forward masking, modulation detection, temporal integration, and pulse rate discrimination show similar performance in implants and acoustic hearing. Implant patients can typically detect silent gaps of 1–3 ms (Shannon, R. V., 1989), show a time constant of about 100 ms for recovery form forward masking (Shannon, R. V., 1990) and temporal integration, and can detect changes in modulation rate or pulse rate up to about 300 Hz (Shannon, R. V., 1983a; Tong, Y. C. *et al.*, 1983; Shannon, R. V., 1992). All of these capabilities are similar to those of normal acoustic hearing, suggesting that these temporal perceptual capabilities are not limited by peripheral synaptic processes. It appears that electrical stimulation, in spite of the considerable differences in the physiological temporal response, produces similar temporal perceptual abilities to acoustic hearing. One study has shown a strong correlation between individual differences in patients' ability to detect modulation and speech recognition (Fu, Q. J., 2002).

3.26.3.3 Spectral (Tonotopic) Coding

One of the places where electrical stimulation is vastly inferior to acoustic hearing is in spatial (tonotopic) resolution. The normal cochlea has more than 5000 inner hair cells that each transmit independent information to auditory neurons. Although longitudinal coupling along the basilar membrane produces some correlation across adjacent hair cells, the biological responses are stochastically independent in time and across location (Johnson, D. H. and Kiang, N. Y., 1976). In contrast, electrical stimulation activates all neurons synchronously within the electrical field of the stimulated electrode (van den Honert, C. and Stypulkowski, P. H., 1987b). Within that region all neurons are activated in a highly deterministic manner, at least for relatively low stimulating pulse rates (below 1000 pulses s^{-1}). Nerve fibers that are adjacent along the tonotopic dimension of the cochlea are all fired in tight neural synchrony by each electrical pulse.

The spatial selectivity of electrical activation is at least partially determined by the configuration of the electrodes. Monopolar stimulation, in which an intracochlear electrode is stimulated relative to a remote ground electrode, produces a broad pattern of activation (Shannon, R. V., 1983b; van den Honert, C. and Stypulkowski, P. H., 1987a). Bipolar stimulation, in which the current source and sink are both intracochlear electrodes that are close to each other, produces activation in a more restricted region. Bipolar electrodes that are more widely spaced produce intermediate activation patterns. Tripolar (also called quadrapolar) electrode configurations, in which a center electrode is activated and the return electrodes flank the active electrode, produces the most restrictive pattern of activation (Spelman, F. A. *et al.*, 1995).

Psychophysically, spatial selectivity can be evaluated with many methods that produce different results depending of the task. Some tasks are quite sensitive to differences in the overlap of the excitation produced by two electrodes while other tasks are not. For example, to discriminate two electrodes may only require that any aspect of the excitation produced by the two electrodes be different. In contrast, loudness may be a relatively insensitive measure of the degree of overlap of the excitation produced by two electrodes: it may require considerable separation of the two excitation patterns to produce a change in loudness (Shannon, R. V. *et al.*, 2004). Recent studies have shown modest differences in perceptual interference for monopolar, bipolar, and tripolar stimulation, broadly consistent with the physiological results (Bierer, J. A. and Middlebrooks, J. C., 2004). However, the perceptual measures appear to be more similar across electrode configurations than the physiological results. One possible explanation for this pattern of results is that the differences in electrode configuration would be expected to diminish if the electrodes are located distant from the nerve to be stimulated. In the physiological experiments the electrodes could be positioned close to the nerves, while in the behavioral experiments the electrodes are likely to be further from the nerves. Overall, there appears to be a modest correlation between psychophysical measures of electrode selectivity and speech recognition (Donaldson, G. S. and Nelson, D. A., 2000).

3.26.4 Speech Recognition

Early single-channel cochlear implants did not produce significant levels of open set speech recognition, but patients still found the sound from the implants to be quite useful and patient acceptance and satisfaction were high. Even single channel implants could provide significant improvements in speech recognition when the sensation produced by the

implant was combined with lip-reading. In addition, the sensation produced by the implant, even when the source of the sound was not identifiable, provided a sense of connection with the world of sound, relieving the isolation of deafness. Many people report that deafness makes them feel isolated and cut off from the world around them. Even minimal hearing provided by a single-channel cochlear implant removed that barrier of silence and made them feel connected again, even if they could not understand speech or identify the sounds.

Multichannel cochlear implants use multiple electrodes to stimulate different tonotopic locations along the scala tympani. Information from the low-frequency region of speech is coded and presented to the most apical electrode location. It is clear that speech recognition improves as the number of spectral channels increases (Fu, Q. J. *et al.*, 1998; Dorman, M. F. *et al.*, 1997), but implant listeners do not appear to be able to utilize all the channels of information presented fully. Although modern cochlear implants have 16–22 electrodes, implant listeners appear to only use a smaller number of effective channels. A study by Fishman K. *et al.* (1997) measured speech recognition in cochlear implant listeners as the number of electrodes was changed. Speech recognition performance increased as the number of electrodes increased only up to four to seven electrodes. From seven to 22 electrodes there was no significant improvement in speech recognition. Even patients who had excellent stimulation selectivity showed no increase in performance as the number of electrodes was increased above seven. A follow-up study (Friesen, L. *et al.*, 2001) showed the same result for speech recognition in quiet and for speech recognition in noise.

One of the most important factors in the tonotopic representation is to preserve the absolute and relative distribution of frequency information in the cochlea, at least as far as is possible with electrical stimulation. Once the brain is highly trained to understand patterns of excitation produced by sound in the normal tonotopic positions in a normal acoustic cochlea, then electrical activation must match that distribution for the patterns to be recognized. If the pattern of nerve activity produced by electrical stimulation is shifted or distorted relative to the normal acoustic tonotopic pattern then speech is not recognized (Shannon, R. V. *et al.*, 1998; Fu, Q. J. and Shannon, R. V., 1999; Baskent, D. and Shannon, R. V., 2003; 2004; 2005). In some cases, speech recognition can be learned even if the sensory pattern is shifted in the cochlea or distorted from the normal acoustic pattern (Fu, Q. J. and Nogaki, G., 2005; Fu, Q. J. *et al.*, 2005a; 2005b). However, congenitally deaf individuals who receive the cochlear implant as adults do not recognize speech with the device even after years of use.

3.26.5 Bilateral Cochlear Implants

Recently hearing-impaired patients have received cochlear implants in both ears in an attempt to restore directional hearing. These trials have demonstrated mixed success, with some implant listeners able to localize sounds in space and others unable to localize. Research is ongoing to determine the factors that lead to binaural fusion and localization with two cochlear implants (van Hoesel, R. J., 2004; Litovsky, R. Y. *et al.*, 2004).

3.26.6 Combined Acoustic and Electric Hearing

The average level of speech understanding with modern cochlear implants is so good that implants are now being applied to patients with relatively good acoustic hearing at low frequencies, but poor to no hearing at mid- and high frequencies. The implant is intended to activate nerves in mid- and high-frequency regions to combine with the acoustic hearing in low frequencies. Preliminary clinical trials are showing mixed success of this approach with some patients showing clear synergy combining acoustic and electric hearing (Gantz, B. J. *et al.*, 2005; Kiefer, J. *et al.*, 2005). Success of an implant in such cases will clearly depend on the survival of neurons in the deafened high-frequency region of the cochlea.

3.26.7 Cochlear Implants as a Tool for Neuroscience

One of the most interesting outcomes of the cochlear implant is in its implications for auditory neuroscience. Although much is known about the function of the cochlea, relatively little is known about central perceptual processing mechanisms in hearing. Cochlear implants have already advanced our knowledge about the interaction between peripheral and central processing in hearing. In people who become deaf as adults, the implant provides

an abnormal and distorted peripheral signal to a well-trained auditory brain. Experiments have demonstrated that a coarse peripheral signal can still produce good speech understanding and poor music understanding. Sound quality and musical pitch require relatively fine information from the periphery whereas pattern recognition of speech requires only relatively coarse peripheral information. Measurements of long-term learning show the plasticity of central processing in adapting to an abnormal peripheral signal (Fu, Q. J. and Nogaki, G., 2005; Fu, Q. J. *et al*., 2005a; 2005b). Children who receive cochlear implants before 2 years of age are showing not only normal speech and language development, but there are also reports of musical abilities that are beyond those available to adult implant patients (Svirsky, M. A. *et al*., 2000). In contrast, congenitally deaf individually who receive the implant as adults derive limited benefit from the implant even after many years of daily use. Central plasticity, critical periods for complex pattern recognition, and the plasticity of early development are all areas in which cochlear implants can provide a tool for research as well as a successful prosthesis.

Glossary

automatic gain control (AGC) Nonlinear hearing aid compression circuitry designed to automatically change gain as signal level changes or limit output when signal level reaches a specified criterion.

conductive loss Reduction in hearing sensitivity, despite normal cochlear function, due to impaired sound transmission through the external auditory meatus, tympanic membrane, and ossicular chain.

feedback Sound produced when an amplification system goes into oscillation, produced by amplified sound from the receiver reaching the microphone and being re-amplified.

minimum audible pressure (MAP) Denotes the sound pressure level (SPL) at the eardrm required by a listener to detect a tone.

over-the-counter (OTC) Hearing aids hearing enhancement devices that provide amplification of sounds, available without the assistance of a hearing professional.

sensorineural loss Hearing loss resulting from damage to the sensory end organs and/or their associated nerve fibers.

signal-to-noise ratio (SNR) Relative difference in decibels between a sound of interest and a background of noise.

SNR loss Increase in SNR, relative to normal-hearing performance, required to understand speech in noise.

sound pressure level (SPL) Magnitude of sound expressed in decibels above the reference level of 20 μpa.

wide-dynamic-range compression (WDRC) A form of automatic gain control that provides greater gain for quiet sounds than for loud sounds, with a smooth change in gain spread out between the two conditions.

3.27.1 Background

There are two difficulties that accompany hearing loss: loss of ability to hear quiet sounds (usually accompanied by a much smaller loss of ability to hear stronger sounds), and loss of ability to understand speech, especially speech in noise. The two losses often but not always go together: either loss can occur without the other. Someone who cannot even detect quiet speech may be able to understand almost as well as someone with normal hearing at an extremely noisy party, while another person who can still detect quiet speech may be unable to understand speech in the presence of noise at any presentation level.

The common term sensorineural loss includes both types of loss whenever they arise from inner-ear or neural pathology. A conductive loss from middle-ear pathology causes a sensitivity loss only. Fortunately, the majority of conductive losses can be treated medically or surgically, and will not be discussed further here.

Hearing aids can do an excellent job of restoring the ability to hear quiet sounds. As discussed below, the task of improving one's ability to hear in noise is much more difficult to solve. Other problems facing hearing aid wearers – feedback (sometimes that only others can hear), a hollow sound in the wearer's own voice called occlusion effect, disappointing sound quality, size, cost, and an unwillingness to see a professional presumably account for the fact that only 20% of those who say they need a hearing aid get one. These issues will be discussed below.

3.27.2 Hearing Loss and Signal-to-Noise Ratio Loss

3.27.2.1 Hearing Loss

The term minimum audible pressure (MAP) denotes the sound pressure level (SPL) at the eardrum required by a listener to detect a tone. As shown in Figure 1, the average MAP for a normal-hearing person is about 12 dB SPL between 500 and 8000 Hz. (The standards specify that MAP be generated by an earphone. Different numbers come from the use of different sound sources and their calibrating methods, but all produce the same eardrum pressure at threshold.)

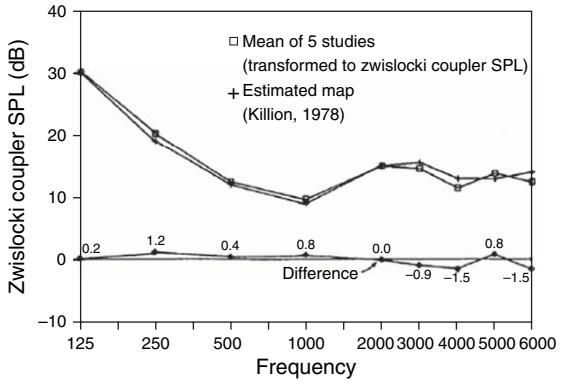

Figure 1 Minimum audible pressure (MAP) at the eardrum estimated from data obtained over a 40-year period (Killion, 1978), plus, five subsequent studies using insert earphones. From Wilber, L. A., Kruger, B., and Killion, M. C. 1988. Reference thresholds for the ER-3A insert earphone. J. Accoust. Soc. Am. 83, 669–676, used with permission.

What is commonly called hearing loss is more precisely called pure tone hearing loss. This is defined as the number of decibels increase in SPL, over normal-hearing response, that is required for a pure tone to elicit a response 50% of the time. It is thus a loss of ability to hear quiet tones; that is, a sensitivity loss. Normal-hearing performance for SPLs at the eardrum that can be detected 50% of the time is shown in Figure 1.

3.27.2.2 Signal-to-Noise Ratio Loss

The second type of hearing loss has recently been dubbed signal-to-noise ratio (SNR) loss, a term derived from the decreased tolerance to noise when the listener is trying to understand speech. Speech is highly redundant. If it was necessary to hear 100% of the available speech cues to carry on a conversation, none of us could enjoy noisy social situations where much of the desired talker's speech is masked by the voices of other talkers. Fortunately, only about 26% of the speech cues must be heard by normal-hearing persons in order for them to understand 90% of sentences correctly. In laboratory experiments, it has been found that it is possible to carry on a conversation with all sounds above 800 Hz filtered out, or all sounds below 2200 Hz filtered out, or even all sounds between 600 and 3500 Hz filtered out, each of which corresponds approximately to removing 75% of the speech cues.

Someone who requires more than 26% of speech cues in order to understand speech is said to have an SNR loss. Rather than express SNR loss in the number of speech cues required, we normally express it as the number of decibels improvement in SNR required to reach normal performance. Normal performance is about 50% words in sentences correct at a roughly 0 dB SNR (signal and noise at equal levels). Three popular tests, the Hearing In Noise Test (HINT), the Quick Speech in Noise (QuickSIN), and the BKB-SIN test each start with a sentence in virtual quiet and progressively increase the noise until the patient can repeat only 50% of the words in sentences correctly. It turns out that if a person requires twice the number of speech cues (i.e., requires 52% instead of 26%) of the cues, he or she will require an 8 dB increase in SNR in order to repeat 50% of the words in sentences correctly.

As shown in Figure 2, patients with similar hearing loss can have dramatically different abilities to

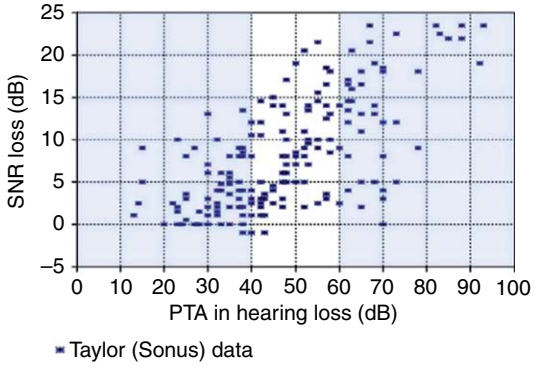

Figure 2 Relationship between signal-to-noise ratio (SNR) loss and pure tone average (PTA) hearing loss for 100 hearing aid wearers. Shaded region of moderate hearing loss shows range of SNR loss from normal (0 dB) to severe loss (23 dB).

understand speech in noise. A loss in sensitivity may or may not be accompanied by a significant loss of ability to hear in noise. For example, an SNR loss ranging from normal (SNR loss = 0 dB) to severely impaired (SNR loss = 24 dB) is found in persons all of whom have a moderate hearing loss.

The distribution in SNR loss among hearing aid wearers has been reported by several groups. Approximately 50% of subjects have a 5 dB SNR loss or greater, 20% have a 10 dB or greater loss, and 5% have a 15 dB or greater loss. A person with a 15–20 dB loss of ability to hear in noise finds it impossible to enjoy a dinner out with family and friends because the restaurant noise makes everyone's normal speech unintelligible to that person.

3.27.3 Hearing Aids

3.27.3.1 Early Hearing Aids

Pre-electric ear trumpets provided acoustic amplification in the 1800s and earlier. In the 1930s, hearing aids consisted of table models, thus the brand name Radio Ear, or relatively large body aids. They used carbon microphones (similar to those used in telephones but generally larger and often used in pairs to obtain 6 dB greater gain), a rheostat as volume control, and an earphone sealed to the ear. The complete electric circuit was battery–microphone–rheostat–earphone–battery. When additional gain was needed, an amplifier consisting of a miniature earphone mechanism connected to a miniature carbon element was added. The carbon element of the earphone was used as an amplifier. Such hearing aids had peak real-ear gains of 50 dB, along with, unfortunately, high distortion and a very peaky frequency response.

By 1952, hearing aids containing miniature vacuum tubes could provide an amount of gain limited only by the quality of the seal (to prevent feedback whistling) between the earmold and the ear. By 1962, continuing miniaturization of the components had made all-in-the-ear hearing aids possible. Figure 3 illustrates the three types which make up the vast majority of hearing aid fittings today. The smallest completely-in-the-canal hearing aids can lie deeply enough in the ear canal to be invisible for all practical purposes.

By the early 1980s, integrated circuits had made improved automatic signal processing possible, the best-known of which was perhaps the Manhatten circuit, which dramatically reduced the distortion for high-level signals by automatically reducing the gain and low-frequency response of the hearing aid as the input sound level increased.

By 1990, zinc–air batteries and high-efficiency class D amplifiers made it practical to provide hearing aids with fidelity equal to the best home stereo systems: 16 kHz bandwidth, low distortion, and an improved signal-processing scheme called wide-dynamic-range compression (WDRC). WDRC is now used in all analog and digital hearing aids. A WDRC amplifier mainly amplifies the quieter sounds, especially the high-frequency sounds rendered inaudible by a typical high-frequency hearing loss, leaving loud sounds with much less amplification. While this approach seems obvious now, it met with great resistance when it was introduced.

Recent data have added further support for providing high fidelity in hearing aids. One surprising – almost astonishing – finding is that the ability of hearing-aid wearers to understand speech in noise can be predicted almost exactly by the fidelity rating given those same aids by normal-hearing subjects, as illustrated in Figure 4. This is counter to common myths, which state that hearing-aid wearers need only digital signal processing and noise reduction, and that limited frequency response is not important.

We find experimentally that hearing-aid wearers assign fidelity ratings nearly identical to those assigned by subjects with normal hearing, further evidence that intelligibility and fidelity are interlinked. More details can be found in Killion M. (2004).

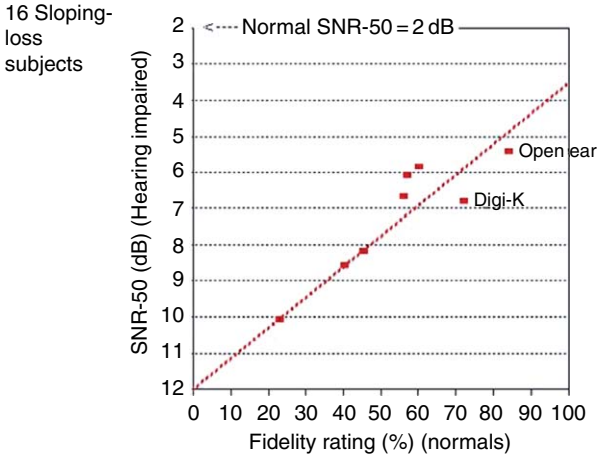

Figure 4 Intelligibility versus fidelity rating for different hearing aid types. SNR, signal-to-noise ratio.

3.27.3.2 Modern Digital Hearing Aids – Limitations

The most recent of the digital hearing aids is probably the cellphone, with its Dick Tracy ability to let us carry on a conversation from almost anywhere in the world. Ironically enough, the emphasis on special features, such as sending pictures, has come at the expense of further improvements in intelligibility. The severe distortion from data compression in today's cellphones results in degradation of 5–6 dB in SNR, measured with QuickSIN tests at a volume control setting of loud but OK, which generally produces maximum intelligibility. Indeed, part of the reason cellphone users speak so loudly that people around them can overhear their conversation is the frequent "what?"

response from listeners who cannot understand. (To be fair, a larger part results from the fact that the candy bar cellphones and Bluetooth cellphones have moved the microphone so far from the mouth that the transmitted SNR is degraded by 20 dB or more compared to the old Western Electric telephone handsets that picked up sound directly in front of the mouth.)

A similar problem in sound quality exists today with some digital hearing aids, whose advertised CD quality contrasts with the reality of distortion (from feedback cancellation, noise reduction, internal time-delay-induced ringing, etc.), ragged frequency response, poor overload characteristics, and improper automatic-gain-control (AGC) time delays. In one example, the AGC action was so fast that the sound of a drummer playing rhythmic shh-shh-shh-shh cymbals sounded more like a nearly continuous shhhhhhhhhhhh.

As of 2002, the typical digital hearing-aid bandwidth was restricted to only 5.8 kHz, which causes a theoretical 0.9 dB (and measured 1 dB) loss in effective SNR for actual hearing aid wearers. In one experiment, the average SNR loss from all causes for seven modern digital hearing aids was 1.7 dB compared to the results with a near-perfect-fidelity amplification system (Killion, M., 2004) using the same subjects. The subjects were 11 hearing aid wearers with flat hearing loss and 16 subjects with sloping loss (greater high-frequency loss).

A 1.7 dB SNR is equivalent to a 17% reduction in the intelligibility of words in sentences, using a test such as the QuickSIN test (Killion, M. *et al.*, 2004). For conversational speech, it represents a 27% decrease in intelligibility in marginal conditions. Fortunately, the best directional-microphone hearing aids provide 5 dB improvement in SNR by rejecting sounds from the back and sides in favor of sounds from directly in front. Interestingly enough, the hearing aids with the best signal processing often contain the best directional microphones, and the manufacturers indicate the performance as Articulation Index–Directivity Index (AI-DI) on the data sheet. (AI-DI is a method used to predict the effect of the directivity on speech recognition performance.) The average directional aids, unfortunately, use directional microphones with only about 3 dB SNR improvement, and usually do not list AI-DI on their data sheets.

Since it has only recently become common practice of audiologists to measure SNR loss, the purchaser of a hearing aid is not always warned in advance that his loss is mostly a loss of ability to hear in noise, so making the sound louder will not help much except in very quiet situations. The patient's high expectations are not always tempered by realistic advice, whether the hearing aids are analog or digital.

3.27.3.3 Modern Digital Hearing Aids – Improvements

Three improvements brought about by the use of digital signal processing are: (1) significant reduction in feedback without reducing the average high-frequency response, (2) the automatic sensing of listening conditions in order to change the circuit configuration, (3) the smoothing of the frequency response and tailoring the response to the desired real-ear response for near-perfect fidelity (used in only a few hearing aids).

What is the practical significance of these improvements? While some feedback reduction schemes accomplish the result by filtering out high-frequency sounds (and thus muffling the incoming speech), the better ones provide increased gain without feedback when the seal of the eartip in the earcanal is lost by chewing, yawning, or even smiling. Thus the better designs represent a real advance for the user with moderate–severe hearing loss. In addition, the improved feedback-rejection methods permit open-ear fittings, where only a thin tube goes into the ear from a behind-the-ear hearing aid. It is now practical to obtain enough gain without feedback for open-ear fittings to be useful for many patients with mild–moderate high-frequency hearing loss. This type of fitting has become increasingly common in recent years, approaching 25% of fittings today.

The automatic sensing of listening conditions has been a boon for many listeners who cannot easily decide (or remember) when to switch between omni- and directional-microphone operation, giving them the optimum omni operation in quiet conditions and directional operation for noisy conditions.

Although digital noise reduction schemes sound attractive in advertisements, to date none has shown any ability to improve intelligibility in noise (except where the hearing aid had been misfit and a side effect of the processing was to improve the fitting). And it is unlikely that any will provide intelligibility improvement in the future, until the hearing-aid circuit can recognize and differentiate between speakers. To explain: most of us have had the experience at a party of hearing the person in front of us drone on tediously, and finding ourselves listening to the left and right for a more interesting conversation (while nodding politely to the person in front at appropriate times). Without

recognition of the speaker by the hearing aid, there is no way for the hearing aid circuit to decide which voice is the desired speech and which voices are part of the interfering babble to be suppressed. The best noise-reduction schemes we have tested do little harm, but no good. The worst cause serious degradation of intelligibility in noise (recall Figure 4).

3.27.4 Satisfaction and Technology

Available surveys show a nearly constant 60% of hearing-aid wearers are satisfied overall (Figure 5). This percentage goes back to as early as 1968, when many people wore body or eyeglass hearing aids, although differences in survey methods prevent direct comparison among the surveys except for the last four conducted by Kochkin K. (2002). Kochkin's surveys cover the period of the transition from analog aids to digital aids, and suggest that the introduction of digital hearing aids did not increase overall satisfaction.

The explanation for these disappointing results appears to lie in the wearer's hearing aid expectations as much as in the hearing aids. Back in 1944, when it was considered a miracle that a simple body-worn hearing aid could provide so much benefit, Hughson W. and Thompson E. (1944) reported a 90% satisfaction rate among those who had purchased their hearing aids from a hospital clinic.

The above history is pertinent today, because for some time hearing aids have solved the audibility part of the hearing loss, but exacerbated the problem of hearing in noise because of their narrow bandwidth. Many hearing-aid input circuits (analog or analog-to-digital converters) are designed to be distortion-free only up to 85–90 dB SPL. At a noisy party where overall levels of 90 dB SPL are not uncommon and resulting speech-peaks reach 100–105 dB, this design choice appears to explain the report of some hearing aid wearers that under those conditions they hear better without their hearing aids. The author has estimated that a deficit equivalent to 6–10 dB in SNR was introduced by the frequency response and distortion of early hearing aids. They were a boon in quiet to those with pure conductive loss (e.g., otosclerosis) and the early carbon-mic aids could handle inputs of 115 dB SPL, but those aids would have been nearly worthless in noise to someone with a 10 dB SNR loss. Indeed, early authors strongly cautioned against fitting someone with nerve deafness, the term used at the time for what we now call sensorineural loss, because of the high failure rate of such fittings. Virtually all hearing aids at the time of Hughson's report were fitted to those with conductive loss; virtually none to those with nerve deafness.

Today, the opposite is true. Because of medical alleviation of most conductive losses, virtually all hearing aids are fitted to those with sensorineural hearing loss, 50% of whom have a 5 dB SNR loss or greater. For those with 0–5 dB SNR loss, their primary problem will be difficulty in hearing quiet sounds and they may be well satisfied with nearly any reasonable hearing aid circuit if properly fitted, especially if the aids contain good directional microphones.

But 40% of hearing aid wearers are dissatisfied with their hearing aids. This includes an estimated 12–16% of US owners who put away their aids in dresser drawers (Kochkin, K., 2000), and an estimated

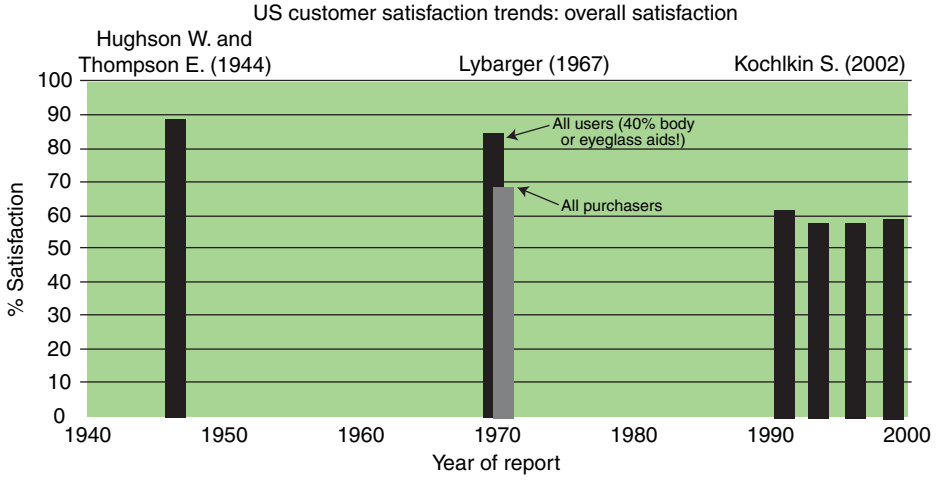

Figure 5 Percentage overall satisfaction with user's hearing aids: data over the years.

25% of owners in England who do the same thing (Davis, A., 2006). Those nonusers presumably include persons whose hearing aids were not properly fitted (or were inappropriate to the loss); those whose earmold fit does not prevent feedback or does not prevent a hollow voice sound; and a small percentage who will not be satisfied with having to wear a hearing aid under any circumstances.

The most important reason for dissatisfaction by those with SNR loss in the 10–15 dB range is their resultant inability to understand speech in the presence of noise at restaurants, parties, etc. Some report that they take off their hearing aids in loud social situations where audibility is not a problem but their inability to separate speech from noise (typically interfering with speech) is. For such persons, the better analog aids and the best digital aids fail equally under those high-noise circumstances: the hearing aids may be solving a problem they do not have in high-level noise (audibility), while failing to solve the problem they do have (SNR loss).

Not surprisingly, user surveys show no difference in overall satisfaction between low-priced analog and high-priced digital hearing aids (Figure 6). One finding is that both types of hearing aids containing directional microphones (Ana Dir and Dig Dir) produce the highest overall satisfaction. Many of the claims that digital circuits are better than analog circuits appear unfounded, based on intelligibility in noise testing, listening tests, and satisfaction ratings.

However, the better digital aids today provide sophisticated feedback reduction that does not simultaneously reduce audibility or intelligibility, and many persons appreciate the convenience of having a digital circuit analyze the sound environment and adjust the hearing aid to the processing the manufacturer has chosen for that environment (directional microphones versus omni microphones), rather than having to readjust the controls. Indeed studies show that many owners of directional hearing aids need this self-adjustment, because they simply leave the hearing aid in the omni setting all the time, even under circumstances when the directional setting would presumably improve their sentence intelligibility by 50–80% (Killion, M. C., *et al.*, 1998).

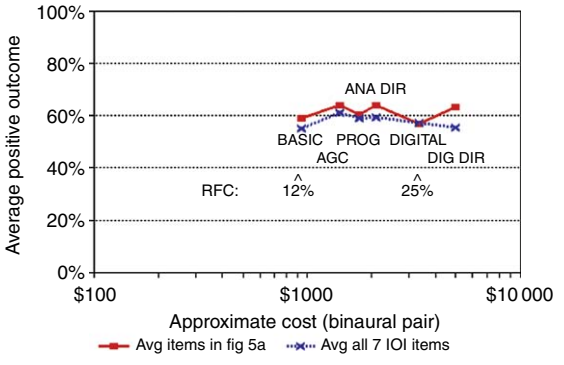

Figure 6 Percentage overall satisfaction as a function of hearing aid cost and technology. No increase with cost or technology is apparent From Van Vliet, D. 2002. User satisfaction as a function of hearing aid technology. Paper presented at: American Auditory Society Scientific/Technology Meeting, 14–16, March, 2002, Scottsdale, AZ.

3.27.5 Over-the-Counter Hearing Aids

Nearly everyone who needs reading glasses in the US gets them, often from the local pharmacy. This option was debated years ago, but no-one now suggests that purchasing over-the-counter (OTC) reading glasses has caused medical damage to the buyers, that they must see a professional to obtain properly fitted reading glasses, that they will be discouraged from buying another pair out of disappointment with the first pair they try, or that OTC reading glasses will destroy the professions of optometry and ophthalmology. Yet analogous arguments have been used to argue the alleged dangers of OTC hearing aids.

Only about 20% of those who need hearing aids in the US choose to purchase them. Several explanations have been offered: the high cost of professionally dispensed hearing aids, a reluctance to see any medical professional, and the failure of friends to be satisfied with their own hearing aids are among them.

With regard to the possible effect of cost, in the US 4.1 persons per 1000 are fitted with one or two hearing aids. Twice that percentage (8.6 per 1000) are fitted with aids in England and three times that percentage (12.4 per 1000) are fitted in Denmark. In both countries hearing aids are free; in the US they cost an average of nearly $3000 a pair (Arlinger, S., 2006). The fact that it takes up to 6 months to get an appointment for a hearing aid fitting in England may influence the lower rate in England.

The percentage of persons who need hearing aids that actually obtain hearing aids can be estimated if the average lifetime of the hearing aids is known. Such an estimate is shown in Table 1, assuming an average life of either 4 years or 7 years for the hearing aids. It appears that 16–29% of those who need hearing aids obtain them in the US, 34–60% in England, and 50–87% in Denmark.

Table 1 Estimate of percentage of those needing hearing aids who get them, assuming the average life of hearing aids is 4 years and 7 years

Country	*# Persons fitted per 1000 inhabitants*	*Percentage ot those needing hearing aids who obtain them if life=*	
		4 years	*7 years*
Sweden	6.3	25%	44%
Denmark	12.4	50%	87%
Norway	7.5	30%	53%
Finland	2.7	11%	19%
Poland	1.3	5%	9%
Netherlands	5.2	21%	36%
Belgium	2.6	10%	18%
Germany	5.5	22%	38%
England	8.6	34%	60%
France			
Australia	8.6	34%	60%
Ontario, Canada	3.9	15%	27%
USA	4.1	16%	29%

Data from Arlinger, S. 2006. A survey of public health policy on bilateral fittings and comparison with market trends: the evidence-base required to frame policy. Int. J. Audiol. 45, S45–S48.

With regard to the possibility that reluctance to see professionals causes the low usage rate in the US, national Medicare statistics indicate that some 60% of those with significant hearing loss have already seen an otolaryngologist, audiologist, or hearing aid specialist, suggesting that most persons who need hearing aids have already received a recommendation to obtain them but chose not to (Freeman, B., 2006, personal communication).

With regard to the argument that only a professional can properly decide if a hearing aid is appropriately fitted, the fact that some 25% of high-end digital hearing aid purchasers return their aids for credit suggests that consumers can and do decide for themselves when a product provides satisfactory service. Similarly, the McLaughlin W. (1995) survey of mail-order hearing aid customers found a satisfaction level of 78%; significantly higher than the 60% reported satisfaction for professionally dispensed hearing aids. One might speculate that obtaining a reasonably adequate hearing aid at one-tenth the price is more satisfactory than obtaining a presumably better fitted digital hearing aid from a professional for $3000.

3.27.6 The Future

Hearing aids at all prices already provide a solution to hearing the quiet sounds that are otherwise missing: grandchildren, quiet speech, and even the songs of distant birds. The better directional-microphone hearing aids can provide significant help for those whose hearing problems include great difficulty understanding speech in noise. In the near future, the technology of assistive listening devices with a microphone for each of three or more talkers will make it possible for virtually everyone having difficulty hearing in noise to enjoy going out to noisy restaurants again.

3.28.1 Ongoing Hair Cell Production in the Ears of Cold-Blooded Vertebrates

The production and replacement of hair cells in the mature ear was first demonstrated in cold-blooded vertebrates. Fishes and amphibians continue to grow throughout life and, as a consequence, new cells are continuously added to most tissues and organ systems. Postembryonic production of hair cells has been observed in the ear of fishes (e.g., sharks, Corwin, J. T., 1981; rays, Corwin, J. T., 1983; teleost fish, Popper, A. N. and Hoxter, B., 1984), frogs (Lewis, E. R. and Li, C. W., 1973), and toads (Corwin, J. T., 1985). The majority of newly produced hair cells arise from division of precursor cells near the edges of the sensory epithelia (e.g., Popper, A. N. and Hoxter, B., 1984; Corwin, J. T., 1985). Given this potential for postembryonic hair cell generation, it is not surprising that these sensory organs can also regenerate lost hair cells (Baird, R. A. *et al.*, 2000; Taylor, R. R. and Forge, A., 2005). All of these studies clearly demonstrate that hair cell production is not necessarily confined to embryonic development, but their direct relevance to warm-blooded vertebrates is unclear. The addition and regeneration of hair cells in mature fishes and amphibians might simply be a consequence of their ongoing growth.

3.28.2 Regeneration in the Avian Ear

Interest in the potential for sensory regeneration in the ear was heightened by the demonstration that the cochlea and vestibular organs of birds can replace hair cells after acoustic overstimulation or treatment with ototoxic antibiotics. Like their counterparts in mammals, the sensory organs of the avian ear do not exhibit continued growth during mature life; hair cell production is mainly confined to a fixed period of embryonic development. Unlike mammals, however, the mature avian ear can quickly generate new hair cells after injury (Cotanche, D. A., 1987; Cruz *et al.*, 1987; Corwin, J. T. and Cotanche, D. A., 1988; Ryals, B. M. and Rubel, E. W., 1988; Weisleder, P. and Rubel, E. W., 1993). Regeneration in the both avian cochlea and vestibular organs has been extensively studied and appears to involve very similar mechanisms. Loss of hair cells leads to an increase in the proliferation of nearby epithelial supporting cells (Figure 1). This response occurs very quickly; supporting cells can enter the S-phase of the cell cycle as early as 12–16 h after hair cell death (Warchol, M. E. and Corwin, J. T., 1996). Also, the number of proliferating cells is related to the extent of the hair cell lesion. Studies of utricles maintained in organ culture have demonstrated that about 1000 supporting cells are in the S-phase of the cell cycle at 48 h after a high-dose streptomycin treatment (Matsui, J. I. *et al.*, 2000). Present evidence suggests that these proliferating supporting cells serve as progenitors for replacement hair cells. They may undergo several rounds of cell division, but ultimately some of the newly divided cells go on to differentiate as hair cells. Once the original hair cell population has been restored, the proliferation of these progenitors ceases. Notably, similar ototoxic injury to the mammalian vestibular organs also leads to the proliferation of supporting cells, but the overall level of cell division is much lower than that observed in the avian ear (e.g., Warchol, M. E. *et al.*, 1993). Finally, there is no evidence for injury-evoked proliferation of supporting cells within the mammalian cochlea (Roberson, D. W. and Rubel, E. W., 1994).

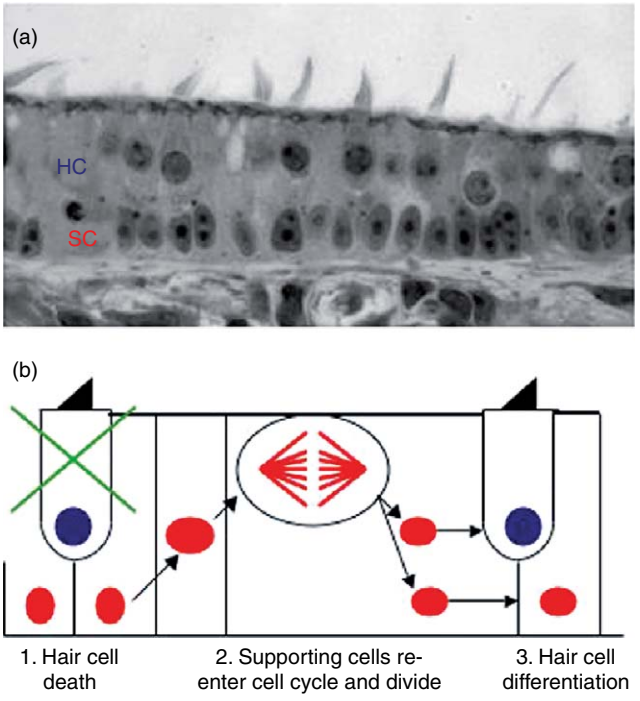

Figure 1 (a) Cross-section of the vertebrate utricle. Hair cell (HC) nuclei reside in the upper stratum of the sensory epithelium, while supporting cell (SC) nuclei are mainly confined to the lower stratum. (b) After hair cell injury, supporting cell nuclei begin to synthesize new DNA and ascend toward the lumenal surface. Cell division takes place near the lumen. The progeny then begin to descend and differentiate as replacement hair cells and supporting cells.

3.28.3 Regulation of Supporting Cell Proliferation

Since proliferation of supporting cells can lead to the production of new hair cells, it is of great interest to understand how cell cycle entry is regulated within the supporting cell phenotype. Much attention has focused on possible signaling near the sites of cell–cell junctions. In the avian ear, all hair cells are linked to their neighboring supporting cells via cell adhesion molecules of the cadherin family (e.g., Raphael, Y. *et al.*, 1988; Warchol, M. E., 2002). Once they die, hair cells are either extruded from the epithelium or are engulfed by nearby supporting cells. In either case, the cadherin-mediated junctions between hair cells and adjoining supporting cells will be disrupted and this may be the initial injury signal. Consistent with this notion, studies of supporting cells in primary culture have indicated that maintenance of N-cadherin-mediated contact is a negative regulator of supporting cell proliferation (Warchol, M. E., 2002). Tyrosine phosphorylation, another common early signaling event in cell cycle entry, is also observed at cell–cell junctions in cultures of proliferating sensory epithelia (Warchol, M. E., 2002). Finally, the proliferation of cultured supporting cells is inversely proportional to the local cell density, suggesting that the ability of a cell to expand its cytoplasm and cytoskeleton can regulate proliferation (Warchol, M. E., 2002). This observation is notable because the apical surfaces of avian supporting cells also contain a novel receptor tyrosine phosphatase, which might deactivate tyrosine kinases (and suppress proliferation) when cells are packed together at high densities (Kruger, R. P. *et al.*, 1999).

The proliferation of nontransformed cells is normally regulated by peptide mitogens, and cultures of such cells typically stop proliferating unless exogenous mitogens are added to the culture medium. In contrast, studies of cultured utricles and their isolated sensory epithelia have suggested that supporting cells produce their own mitogens, which then act in an autocrine or paracrine fashion (Warchol, M. E. and Corwin, J. T., 1993; Warchol, M. E., 1995). The identity of the mitogens(s) that regulate proliferation in the avian ear remains uncertain. Proliferation of cultured supporting cells can be moderately increased by treatment with insulin, insulin-like

growth factor-1 (IGF-1), transforming growth factor-α (TGF-α), and tumor necrosis factor-α (TNF-α; Oesterle, E. C. *et al.*, 1997; Warchol, 1999), and decreased by treatment with fibroblast growth factor-2 (FGF2) and transforming growth factor-β1 (TGF-β1; Warchol, M. E., 1999; Oesterle, E. C. *et al.*, 2000). Unfortunately, there is little direct evidence to date for the involvement of any of these factors in the regenerative process *in vivo*.

More recent studies have focused on identification of downstream signaling pathways that are activated in response to injury. Signaling via a cyclic-adenosine monophosphate (AMP)-dependent pathway can induce proliferation in the avian cochlea and the mammalian vestibular organs (Navaratnam *et al.*, 1996; Montcouquiol, M. and Corwin, J. T., 2001a). Activation of the phosphatidylinosital-3-kinase (PI3-K) is also required for supporting cell proliferation (Montcouquiol, M. and Corwin, J. T., 2001b; Witte, M. C. *et al.*, 2001). In addition, several transcription factors have been implicated in regenerative proliferation. The homeoboxlike factor cPROX1 is expressed in hair cell progenitors during both embryonic development and regeneration (Stone, J. S. *et al.*, 2004). The paired box factor PAX2 is associated with regions of cell proliferation in the developing inner ear (Li, H. *et al.*, 2004), and expression of this factor is maintained in the vestibular organs of mature birds (Warchol, M. E., 2007). At present, several groups are using microarray methodology to examine large-scale changes in gene expression during regeneration (e.g., Hawkins, R. D. *et al.*, 2003). Such studies have the potential to identify the specific regulatory pathways that promote regeneration in the avian ear.

3.28.4 Recovery of Hair Cells and Sensory Function

Supporting cells continue to proliferate for several days after hair cell injury. Beginning about 48–72 h after injury, a subset of the progeny start to differentiate as replacement hair cells. In the chick cochlea, new hair cells are observed as early as 3 days after acoustic injury and reasonably complete repair of the sensory epithelium is apparent after about 10–14 days (Cotanche, D. A., 1987; Corwin, J. T. and Cotanche, D. A., 1988). Because they require systemic treatment with ototoxic drugs, studies of regeneration in the avian vestibular organs typically involve longer time courses. Treatment for 5–7 days with a moderate dose of streptomycin results in the death of nearly all hair cells in the striolar region of the utricle (e.g., Weisleder, P. and Rubel, E. W., 1993; Matsui, J. I. *et al.*, 2003). Hair cells in this region begin to reappear after about 2 weeks, but recovery is still incomplete after 8 weeks (Warchol, M. E. and Speck, J. D., 2007). Specification of hair cell phenotype in the regenerating ear is accomplished via a Notch–Delta interaction, whereby a differentiating hair cell actively inhibits its neighboring cells from taking on a hair cell phenotype (Stone, J. S. and Rubel, E. W., 1999). A very similar mechanism specifies hair cell fate during embryonic development (Adam, J. *et al.*, 1998). Finally, numerous studies have demonstrated nearly complete return of auditory and vestibular function after regeneration (reviewed in Bermingham-McDonogh, O. and Rubel, E. W., 2003).

3.28.5 Regeneration in the Absence of Cell Proliferation

Most studies of regeneration in the hair cell epithelia of fishes, amphibians, and birds have pointed to a key role for supporting cell proliferation in the regenerative process. Thus, it is somewhat surprising that a significant amount of hair cell recovery can be observed in these organs even when cell proliferation has been blocked by treatment with antimitotic drugs (e.g., Adler, H. J. *et al.*, 1997; Steyger, P. S. *et al.*, 1997; Baird, R. A. *et al.*, 2000). Also, during ordinary regeneration, a small number of new hair cells can be produced by means other than proliferation (Roberson, D. W. *et al.*, 2004; Taylor, R. R. and Forge, A., 2005). In both of these cases, regenerated hair cells appear to arise by (at least) two distinct mechanisms. First, aminoglycoside treatment does not always lead to the complete death of target hair cells. Instead, a subset of injured hair cells appear to lose their stereociliary bundles and cuticular plates, but remain alive within the sensory epithelia. These surviving hair cells can then grow new stereocilia bundles (Zheng, J. L. *et al.*, 1999; Gale, J. E. *et al.*, 2002). Also, some supporting cells appear to be capable of changing directly into new hair cells, without first undergoing proliferation (e.g., Adler, H. J. *et al.*, 1997; Li, L. and Forge, A., 1997; Roberson, D. W. *et al.*, 2004). The cellular basis of phenotypic conversion has been particularly difficult to study, since there is no unambiguous method of labeling and identifying cells that have undergone a phenotypic change.

3.28.6 Summary

Although much has been learned about the basic biology of hair cell regeneration, most of the fundamental questions remain unanswered. Taken together, the results summarized above suggest that regenerative ability is critically linked to the capacity for cellular proliferation within the mature ear, even when replacement hair cells are not produced via cell division. One key unanswered question is: how is cell cycle entry differentially regulated within the supporting cells of mammals and nonmammals? In order to resolve this issue, it will first be necessary to identify the signaling pathways and transcriptional regulators that maintain the differentiated state and/or permit proliferation in nonmammalian supporting cells. Finally, it is notable that mammals are the only vertebrates that lack the capacity for hair cell regeneration. This suggests that regenerative ability is the default condition of vertebrate ear, and it will be of great interest to understand why regenerative ability has been lost from the mammalian ear and which genetic modifications are responsible for its absence.

Glossary

gene therapy Treatment by replacing, supplementing, or manipulating the expression of genes with the introduction of genetic material or genes.

liposomes Artificial, single or multilaminar vesicles made from lipids that can be used for the delivery of a genes to cells.

round window membrane A trilaminar membrane that separates the basal turn of the cochlea from the middle ear space.

viral vector A gene transfer vehicle composed of viral DNA and usually containing a therapeutic or experimental gene of interest.

3.29.1 Introduction

Congenital and acquired sensorineural hearing loss is the most prevalent inherited sensory disorder associated with significant morbidity and deterioration in quality of life. Despite its prevalence, therapeutic intervention is limited to assistive electrical devices such as frequency modulation (FM) systems, hearing aids, and cochlear implants that partially restore audition. While these technologies objectively and subjectively improve hearing, as well as the patient's quality of life, significant shortcomings of electrical rehabilitation remain including poor sound localization, inadequate clarity of hearing especially in background noise, and inability to appreciate complex auditory signals such as music. These technologies fail because they do not regenerate or recreate the physiologic mechanism of hearing. Gene therapy holds the promise of restoring natural, high-fidelity hearing by re-establishing normal physiology.

The potential to introduce normal genes to replace defective ones to restore normal function was suggested nearly 30 years ago by Friedmann T. and Roblin R. (1972). Over the past three decades, several lines of research elucidating normal biology and physiology of hearing have raised the expectation that gene therapy may play a role in the treatment of hearing disorders. These include the demonstration of avian inner hair cell regeneration in the late 1980s (Corwin, J. T. and Cotanche, D. A., 1988; Ryals, B. M. and Rubel, E. W., 1988) with the recent identification of handful of genes important in inner ear and hair cell development and regeneration (e.g., math1, retinoblastoma protein) (Bermingham, N. A. *et al.*, 1999; Cotanche, D. A., 1999; Kawamoto, K. *et al.*, 2003; Sage, C. *et al.*, 2006). In the 1990s, a variety of growth factors were shown to mitigate inner ear damage following ototoxic insult; however, their effect was temporally limited and waned with physiologic breakdown of the protein. Methods for increasing availability of the growth factor over time, possibly with gene therapy, were needed. Over the last decade, rapid discovery of nearly 75 genes responsible for nonsyndromic deafness has led to the elucidation of the molecular basis for hearing and hearing loss. The identification of molecular targets to arrest, prevent, or restore hearing loss has spurred the development of cellular and molecular therapies and it has come to occupy a significant portion of current otologic research.

Gene therapy is the introduction of genetic material for therapeutic benefit by the process of gene transfection. Both viral and nonviral vectors have

been used for gene transfection and each is associated with its advantages and disadvantages. The objective of this review is to examine viral gene transfection.

3.29.2 Viral Vectors: An Overview

Since Smithies O. *et al.* (1985) reported the first chromosomal gene targeting in mammalian cells in 1985, both viral and nonviral vectors have been used for the transfection of eukaryotic cells. However, viral vectors have several advantages over nonviral vectors given their innate ability to infect human cells including a specific mechanism for cell binding and entry, an efficient targeting mechanism of the transgene to the nucleus of the cell, and avoidance of intracellular degradation. Additionally, virions are able to use the host cell's machinery to express the viral genome. In order to prevent host cell lysis via immune-mediated processes, the viral agents are usually altered so that they can no longer replicate within the transduced cell. Viral gene delivery has been performed using a number of different viruses including both DNA (e.g., adeno-, adeno-associated-, and herpes) and RNA (e.g., retro- and influenza) viruses. Each is characterized by both desirable and undesirable characteristics that make them more or less suitable for gene therapy and none is ideal for all applications.

The first viral vector used for mammalian gene targeting and the prototype for viral-mediated gene transfer is the retrovirus murine leukemia virus (Ellis, J. and Berstein, A., 1989; Berkener, K. L., 1992; Merrouche, Y. and Favrot, M. C., 1992). Retroviruses are RNA viruses that are reverse transcribed into DNA and are able to integrate into the host chromosome of dividing cells. Thus, in rapidly proliferating cells such as cancer cells, they are ideal for stable long-term transgene expression and have been extensively used in both *in vivo* and *in vitro* cancer models. However, retroviral DNA expression in eukaryotic host cells has been shown to activate a cascade of sophisticated defense mechanisms designed to reject the retrovirus as foreign thereby leading to its inactivation (Bestor, T. H. and Tycko, B., 1996; Bestor, T. H., 2000). Additionally, the neurosensory epithelial cells of the cochlea are postmitotic, making retroviral vectors unsuitable for cochlear gene therapy.

Unlike other retroviral vectors, the lentiviral vector, based on the human immunodeficiency virus (HIV), can integrate into both dividing cells as well as nondividing cells leading to stable long-term expression of the transgene (Naldini, L. *et al.*, 1996). This would make the lentivirus an ideal candidate for gene transfection of the postmitotic cochlear neuroepithelia and spiral ganglions. *In vivo* infusion of the lentivirus vector via a cochleostomy into a guinea-pig cochlea revealed a highly restricted fluorescence pattern limited to the periphery of the perilymphatic space and spiral ligament suggesting limited distribution of the large virus within the cochlea or inability to transfect the other inner ear cell types (Han, J. J. *et al.*, 1999). *In vitro*, lentivirus was able to transduce auditory neurons thus suggesting that it is limited physical distribution that is responsible for the restricted transfection pattern seen. While robust in transfection efficiency and facilitates long-term transgene expression, concerns remain about the use of a HIV-based vector in human trials.

Like the retroviruses, the adenovirus is a well characterized and extensively studied viral vector for gene therapy applications; it has also been shown to be an effective vector for intracochlear gene transfer (Raphael, Y. *et al.*, 1996; Staecker, H. *et al.*, 2001). This vector is highly effective for transient gene transfer due to its capacity for introducing large foreign genes, the ability to transduce both dividing and nondividing cells with high efficiency, and the relative ease with which it can be produced in high titers (Friedmann, T., 1997). However, the transgene expression is temporally limited as adenovirus does not integrate into the host cell genome and the recombinant gene is expressed as an extrachromosomal element for a period of only several weeks. The native adenovirus also provokes a strong immune response that can cause significant tissue damage *in vivo*, thereby limiting its usefulness. Newer generations of attenuated adenovirus vectors have deleted viral sequences making them less immunogenic; however, their efficacy in the cochlear microenvironment still awaits validation.

Adeno-associated viruses (AAVs) are able to overcome some of the shortcomings of the adenovirus. AAV is a single-stranded DNA parvovirus endogenous to diverse mammalian species and is not known to cause any disease in humans. Its ability to infect and integrate into both dividing and nondividing cells with high frequency makes it an ideal candidate for work on quiescent cells of the inner ear. AAV can persist as an integrated provirus without lyses of the host cell; if the host cell is superinfected with a helper virus (adenovirus or herpes virus), the integrated AAV genome is able to carry out lytic growth. AAV

has previously been used for the long-term correction of hemophilia B in a dog model (Herzog, R. *et al.*, 1999; Mount, J. D. *et al.*, 2002; Arruda, V. R. *et al.*, 2005) and has been shown in phase I trials to result in successful, dose-dependent gene transfer of the cystic fibrosis transmembrane conductance regulator (CFTR) gene into the maxillary sinus of patients with cystic fibrosis and sinusitis (Wagner, J. A. *et al.*, 1999). A major disadvantage of AAV is its small packaging limit, restricting the size of potential transgenes to 4.5 kb of DNA.

Herpes simplex virus (HSV) is a double-stranded DNA virus with demonstrated tropism for mammalian neural tissues. HSV is a relatively large virus with several characteristics, which make it an attractive vector for gene therapy: broad host cell range with vectors that are highly infectious; the ability to infect nondividing cells with efficient transduction; a large proportion of nonessential viral genes allowing accommodation of multiple or large transgenes (Krisky, D. M. *et al.*, 1998); and the latent behavior of the virus allowing stable long-term expression of the transgene (Lachmann, R. H. and Efstathiou, S., 1997). HSV-1 has been used as a vector for inner ear gene transfer in mammals (Derby, M. L. *et al.*, 1999); however, its use is limited. These vectors are difficult to produce, have low infection efficiency, and many people have been previously infected by this virus, with subsequent immunity to various components of HSV.

3.29.3 Gene Therapy and Hearing Impairment: Cochlear Gene Transfer

The feasibility of gene therapy as a therapeutic strategy for hearing loss rests on the elucidation of the cellular and molecular targets of hearing. While much progress has been made in the last decade, and genes for both syndromic and nonsyndromic hearing loss have been discovered and proposed as potential therapeutic targets, gene therapy for hearing disorders is still not ready for clinical application. Current focus of inner ear gene therapy is largely on the manipulation of genes responsible for hair cell regeneration and the introduction of neurotrophic factors to promote neuronal survival. Nonetheless, substantial progress has been made in the exploration of the potential of gene therapy for inner ear disorders.

Lalwani A. K. *et al.* (1996) and Raphael Y. *et al.* (1996) independently reported on the feasibility of intracochlear transfection using AAV and adenovirus vectors, respectively, in the guinea-pig. Using β-galactosidase as a reporter gene, the AAV vector was found to transduce nearly all tissue types in the cochlea, including spiral limbus, spiral ligament, spiral ganglion, and the organ of Corti; however, the stria vascularis did not show transgene expression (Figure 1). The marker gene expression was shown to be present for up to 24 weeks following osmotic minipump-mediated infusion of the AAV-β-galactoside vector. Adenovirus-mediated gene transfer was characterized by expression of the reporter gene in nearly all cell types including stria vascularis; however, the expression was temporally limited and an immune response was noted. Subsequently, a variety of vectors have been successfully used to mediate gene transfer to the inner ear including AAVs (Lalwani, A. K. *et al.*, 1998a; 1998b), lentiviruses (Han, J. J. *et al.*, 1999), HSV type 1 (Geschwind, M. D. *et al.*, 1996; Jin, B. K. *et al.*, 1996; Staecker, H. *et al.*, 1998; Van de Water, T. R. *et al.*, 1999), retroviruses (Zheng, J. L. *et al.* 1998), and adenoviruses (Raphael, Y. *et al.*, 1996; Weiss, M. A. *et al.*, 1997; Yagi, M. *et al.*, 1999) and the features of viral-mediated gene transfer has been further characterized. Table 1 summarizes the characteristics of cochlear transgene expression with different viral vectors, with differences likely reflecting the unique properties of the vectors such as size of the viral particle, presence or absence of viral receptors, promoters used, or differences in host cell susceptibility to infection.

While the seminal work on auditory gene transfection was performed using guinea-pigs, subsequent studies have shifted their focus to using the mouse as the animal model. The mouse genome is better characterized than that of the guinea-pig. There are a number of available mutant mice strains with inherited hearing loss, with the genetic basis of their hearing loss identified (Avraham, K. B., 2003). Additionally, transgenic mice have been generated in order to study the knockout effect of mutant alleles on nonsyndromic and syndromic hearing loss (Anagnostopoulos, A. V., 2003).

3.29.4 Intracochlear Viral Gene Delivery

Delivery of viral vector to the cochlea can be accomplished via systemic administration of the virus, intratympanic injection, or direct intracochlear administration (Figure 2). The potential for systemic delivery of viral vector for inner ear therapy is

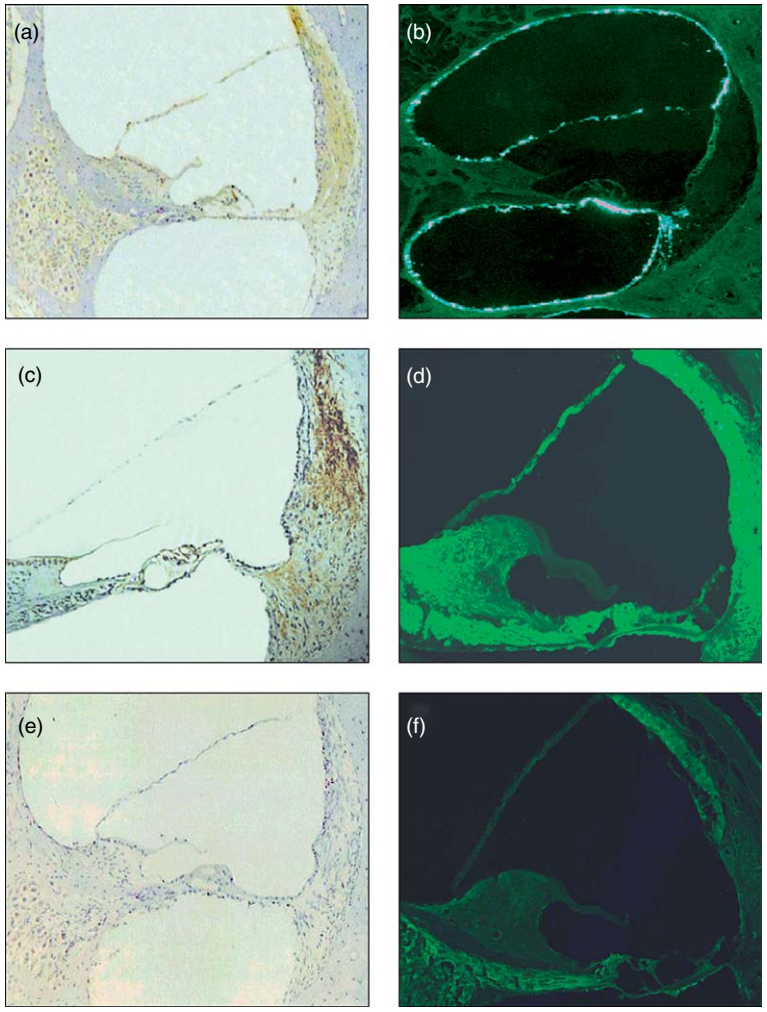

Figure 1 Intracochlear transgene expression. (a) Liposome- and (c) adeno-associated virus (AAV)-mediated beta-galactosidase (β-gal) transgene expression within guinea-pig cochleae. (b) Lentivirus- and (d) liposome-mediated humanized green fluorescent protein (GFP) transgene expression within (b) guinea-pig and (d) mouse cochleae. Transgene expression of β-gal or GFP following infusion (a–c) and direct instillation through the intact round window membrane (d) is seen ipsilaterally in the cochleae, but not in the control cochleae (e, f). Reprinted with permission from Anil K. Lalwani, MD, New York University School of Medicine.

Table 1 Transfection of cochlear cells and tissues by viral vectors

Vector	*Hair cells*	*Supporting cells*	*Auditory neurons*	*Stria vascularis*	*Reissner's membrane*	*Spiral ligament*	*Immune response*
AAV	+	+	+	−	+	+	−
Adenovirus	+	+	+	+	+	+	+
Herpes virus	−	+	+	−	+	+	+
Vaccinia	+	+	−	−	+	+	+
Lentivirus	−	−	+	−	+	+	−
Liposomes	+	+	+	−	+	+	−

AAV, adeno-associated virus.

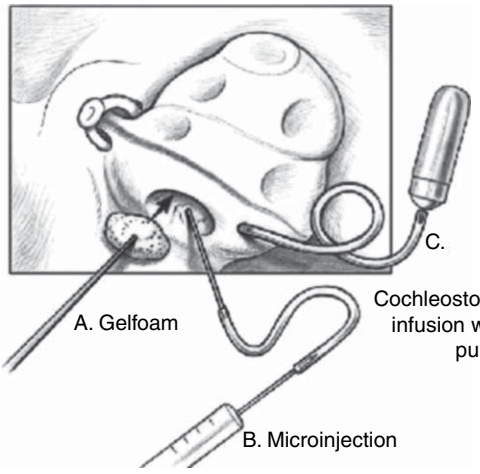

Figure 2 Routes of delivery for cochlear gene therapy. The delivery of a therapeutic agent to the cochlea can be performed by: direct instillation of the agent through an intact round window membrane with a gelatin sponge (A); direct injection through the round window membrane (B); and, infusion with osmotic minipump through cochleostomy (C). Reprinted with permission from Anil K. Lalwani, MD, New York University School of Medicine.

hampered by the blood–cochlear barrier preventing efficient delivery, the relatively limited cochlear blood flow compared to the remainder of circulation, and potential for unwanted systemic toxicity (Wareing, M. J. and Lalwani, A. K., 1999). Intratympanic delivery with subsequent diffusion of the vector across the round window membrane (RWM) is attractive as it avoids systemic toxicity. This route has the additional advantage of significant prior clinical experience as various pharmacotherapeutic agents (e.g., aminoglycosides, steroids) are routinely administered in this manner (Jero, J. *et al.*, 2001a). However, the permeability of RWM is quite variable depending on the conditions of the middle ear, the anatomy of the area, the presence or absence of mucosal adhesions obstructing the round window, and the nature of the administered agent including its charge and size. Direct gene transfer to the inner ear via injection or perfusion through a cochleostomy is conceptually preferable as the virus is delivered directly to the organ of interest with restricted distribution; the dose of the virus can also be controlled. However, direct intracochlear introduction can be associated with hearing loss.

To date, several methods of *in vivo* gene delivery to the inner ear have been tested. Most studies have used either a cochleostomy through the basal turn of the scala tympani (Lalwani, A. K. *et al.*, 1996; Carvalho, G. J. and Lalwani, A. K., 1999; Han, J. J. *et al.*, 1999) or via the RWM in order to deliver the vector to the perilymphatic space (Raphael, Y. *et al.*, 1996; Derby, M. L. *et al.*, 1999; Yagi, M. *et al.*, 1999). Other methods such as endolymphatic sac injection (Yamasoba T. *et al.*, 1999), posterior semicircular canalostomy (Kawamoto, K. *et al.*, 2001), and scala media injection via cochleostomy (Ishimoto, S. *et al.*, 2002) have also been attempted with varying success. Due to the small volume of perilymphatic fluid within the scala tympani of mice and guinea-pigs (~5 and 12 µl respectively) (Thorne, M. *et al.*, 1999), infusion methods such as osmotic minipumps (Davies, E. *et al.*, 1994) and microinjections are used with RWM or scala tympani exposure in order to protect against disturbance of the delicate fluid homeostasis. Despite these precautions, introduction of viral vectors with a miniosmotic pump through a cochleostomy has been shown to incite an inflammatory response and connective tissue deposition adjacent to the site (Davies, E. *et al.*, 1994) as well as causing a mild to marked rise in ABR thresholds at mid- and high frequencies, respectively (Carvalho, G. J. and Lalwani, L. K., 1999). Recently, noninvasive infusion of the gene vector via gelfoam soaked with a therapeutic agent against the round window has been demonstrated with minimal elevation of postoperative ABR thresholds. This technique is minimally invasive, avoids direct manipulation of the cochlear apparatus and iatrogenic hearing loss, as well as reduces dissemination outside the target cochlea, making it a clinically viable option for human gene therapy in the future (Jero, J. *et al.*, 2001a; 2001b).

3.29.5 Cochlear Gene Therapy: Safety Considerations

Lalwani A. K. *et al.* (1996) initially reported the potential of transgene expression at a distant site following cochlear infusion of viral vector. Utilizing AAV as the gene therapy vector, they observed transgene expression within the contralateral cochlea of the AAV-perfused animal, albeit much weaker than within the directly perfused cochlea (Lalwani, A. K. *et al.*, 1996). Expression of the transgene within the contralateral cochlea raises concern about the risks associated with dissemination of the virus from the target tissue. The appearance of the virus, distant from the site of infection, may be due to its hematogenous dissemination to near and distant tissues. However, this is unlikely as the viral vector was not

detected in near and distant tissues. Other possible explanations include migration of AAV via the bone marrow space of the temporal bone or via the cerebrospinal fluid (CSF) space to the contralateral ear (Kho, S. T. *et al.*, 2000). The perilymphatic space into which the virus was perfused is directly connected to the CSF via the cochlea aqueduct; transgene expression within the contralateral cochlea aqueduct has been demonstrated following introduction of the viral vector in the ipsilateral cochlea. Collectively, these results suggest potential routes for AAV dissemination from the infused cochlea via the cochlea aqueduct or by extension through the temporal bone marrow spaces. The potential for leakage from the infused cochlea can be diminished or eliminated by avoiding continuous infusion; when a smaller volume of injection was used in the cochlea, contralateral transgene expression was not seen.

3.29.6 Viral Gene Therapy: Preclinical Applications

Although viral gene therapy for hearing loss has not yet been attempted in human subjects, it has shown to be efficacious in animal models. First, several transgenic products expressed in the cochlea have been shown to protect the sensory hair cells and primary auditory neurons against atrophy and degeneration following ototoxic exposure. Using virally transduced brain-derived growth factor (BDGF) in the inner ear, Staecker H. *et al.* (1998) were able to show a survival effect on spiral ganglion neurons exposed to toxic levels of aminoglycoside. Similarly, Lalwani A. K. *et al.* (2002) demonstrated the protective effect of AAV-mediated BDNF expression on spiral ganglion neurons exposed to aminoglycoside both *in vitro* and *in vivo* with region specificity – the protection occurred predominantly at the basal turn of the cochlea with relative sparing of the middle and apical regions. Other investigators have shown protective effects of neurotrophin-3 (NT-3) (Chen X. *et al.*, 2001; Bowers, W. J. *et al.*, 2002) and glial-derived nerve growth factor (GDNF) on the spiral ganglion cells and hair cells (Yagi, M. *et al.*, 1999; 2000).

A second application of viral gene therapy has been in the introduction of antioxidant gene expression to counteract reactive oxygen species in the inner ear. Oxygen radicals are thought to play a role in many of the mechanisms of acquired hearing loss, and free radical scavengers such as superoxide dismutase (SOD) have demonstrated protective effects on hearing damage secondary to noise exposure (Seidman, M. D. and Shivapuja, B. G., 1993), aging (McFadden, S. L. *et al.*, 1999), and aminoglycoside treatment (Kawamoto, K. *et al.*, 2004). Although these trials have only been performed in animal models, the preservation of hair cells and auditory thresholds in the treated animal population offers the hope for future treatment potential in humans.

Finally, and perhaps most exciting, is the use of gene transfer technology to induce the differentiation of organ of Corti cells toward hair cell fates – a preliminary step toward hair cell regeneration. The auditory sensory epithelia within the organ of Corti are terminally differentiated cells that lack basal stem cells. For this reason, it was long assumed that regeneration of damaged or lost hair cells could not occur. However, as was shown in the avian inner ear, supporting cells can be induced to change their phenotype and become new hair cells (Corwin, J. T. and Cotanche, D. A., 1988; Ryals, B. M. and Rubel, E. W., 1988). Recently *math1* or *atoh1*, a basic transcription factor, already known to induce hair cell differentiation during development of the cochlea (Bermingham, N. A. *et al.*, 1999), was shown to have similar effects in the adult (Kawamoto, K. *et al.*, 2004) mammalian cochlea. Using viral transfection and subsequent overexpression of the *math1* gene in the inner ear, Kawamoto K. *et al.* (2004) showed the induction of rudimentary hair cell growth in ectopic locations near the organ of Corti with some auditory function.

3.29.7 Future Implications

The past 10 years of research in cochlear gene therapy has shown that viral transfection for hearing disorders holds significant promise. There is great deal of excitement of its potential to improve rehabilitative outcomes in patients with cochlear implants with concomitant gene therapy (with neurotrophic factors allowing for outgrowth of auditory neuronal processes toward the implant electrode). Perhaps fetal genetic screening will someday include tests for known genetic mutations causing both syndromic and nonsyndromic hearing loss, and *in utero* gene therapy using viral vectors could ameliorate congenital deafness. As our understanding of gene therapy using viral vectors for the inner ear improves, and translational research shifts from the laboratory bench to the bedside, several concerns will need to be addressed. Safety issues regarding gene therapy using viral vectors have been raised in the wake of

three children, all having received gene therapy for severe combined immunodeficiency in France, developing leukemia-like lymphoproliferative malignancies (Hacein-Bey-Abina, S. *et al.*, 2003). Regulation of gene expression, specifically regional and distant dissemination of the therapeutic agent, will need to be optimized. Finally, surgical procedures that minimize both damage to the inner ear microarchitecture and hearing loss will need to be perfected. Gene therapy using viral transduction has shown significant advances in the last decade. These advances will serve as the foundation for the introduction of novel gene therapeutics for the inner ear in the future.

Glossary

chopper cells A physiological term to describe neurons with regular chopping discharge patterns characterized by narrow initial peaks in poststimulus time histograms.

clade A taxonomic group of organisms consisting of a single common ancestor and all the descendants of that ancestor.

interaural level difference (ILD) The difference between sound levels at the left versus the right ear; used by the central nervous system to compute sound source location.

interaural time difference (ITD) The difference between the timing of the sound stimulus to the left versus the right ear; used by the central nervous system to compute sound source location, in particular, azimuth.

monophyletic A group consisting of an inferred common ancestor and all its descendants.

nucleus As used in anatomy to describe a grouping of cells that form a functional unit; often, but not always, there is a dominant cell type (e.g., fusiform or multipolar cells).

onset cells A physiological term to describe neurons that fire at the beginning of the stimulus and are often silent thereafter.

phase-locking A physiological term based on a cell's ability to encode the phase of a sinusoidal stimulus. Phase-locking is quantified using the

coefficient of synchronization (R) to calculate the probability that the cell will fire at the specified phase.

phasic A physiological term based on a cell's response to a specific stimulus; the cell generally responds at the onset of stimulation, but not throughout (cf. tonic).

polyphyletic A group is polyphyletic if the trait its members have in common evolved separately in different places in the phylogenetic tree. Equivalently, a polyphyletic taxon does not contain the most recent common ancestor of all its members.

tonic A physiological term based on a cell's response to a specific stimulus; the cell fires continuously as long as the stimulus is presented at an appropriate level (cf. phasic).

3.30.1 Introduction

Members of all vertebrate groups have sensory receptors to detect sound energy, though there is much diversity in their capabilities. Within each vertebrate group, there are species for which hearing is critical for normal behavior. In this chapter we will concentrate on how the nervous system encodes particular characteristics of sound along the auditory pathway from the ear to the highest levels of the brain. Our approach to the neuroanatomy will therefore have a functional slant. Emphasis will be placed on how sound becomes categorized by the brain, as needed to sort out the biologically relevant components from the auditory scene. For a detailed discussion of the concept of auditory scene, the reader is referred to Chapter Auditory Scene Analysis.

Sound is a longitudinal wave of alternating pressure increases (compressions of the molecules in the medium) and decreases (rarefactions of the molecules in the medium). Hearing is something quite different. An old question is pertinent here: if a tree falls in the forest, does it make a sound if no one is there to hear it? There can be no doubt that the impact of the tree on the forest floor will make vibrations that could be detected as sound in the air and in the surrounding ground, but it is not heard unless there is an animal with a specialized receptor present in the air or ground. Hearing requires the transformation of the energy in a sound wave to a code that the nervous system can use. There are two components to sound that can be detected by the auditory systems in animals: pressure changes and/or particle motion. In this chapter, we will discuss the process by which sound in the environment is perceived by vertebrates and encoded in a way that is useful to the nervous system.

3.30.1.1 Sensory Receptors

The sensory receptor for the transduction of sound to electrical signals in all vertebrates is a mechanoreceptor that responds to deformation of its surface structures. This mechanoreceptor has been called a hair cell due to the shaggy appearance of the surface structures in the earliest laboratory examinations of the ear. The hair cell varies somewhat in its form among vertebrate groups and the response properties of the cells vary as well (see Chapter Phylogeny and Evolution of Ciliated Mechano-Receptor Cells). In general, there are rows of stereovillae in a very orderly, stair-step array on the surface of the cell. The relative movement of the stereovillae is influenced by an overlying or associated structure, such as a gelatinous cupula, a suspension of small calcareous otoconia, a dense calcified otolith connected to the stereovillae via a gelatinous matrix, or a tectorial membrane. For further details about the structural variations and the distribution of hair cell types among vertebrates, see Chapter Phylogeny and Evolution of Ciliated Mechano-Receptor Cells. For this chapter, we will briefly describe the qualities of the hair cell that are related to response properties of unique importance to each vertebrate group.

Auditory hair cells are always found in groups on an epithelium (or macula) that also contains supporting cells (Figure 1). The base of the cell is within the epithelium, and the stereovillae extend from the apical surface of the cell into a fluid (endolymph). The stereovillae vary in length and stiffness, both of which affect the frequency responsiveness of the individual cell. For example, hair cells with long stereovillae respond best (produce the greatest output to an afferent neuron) to lower frequencies than do hair cells with short, stiff stereovillae. In addition, the stair-step array of stereovillae imposes directionality to the responsiveness of the hair cell.

Bending of the hair cell stereovillae along the cell's best axis results in maximum excitation of the hair cell and maximum neurotransmitter release to the postsynaptic afferent neuron. Bending of the stereovillae in the opposite direction (180° difference in the axis of stimulation) causes the cell to hyperpolarize to its maximum extent, meaning that the hair cell does not

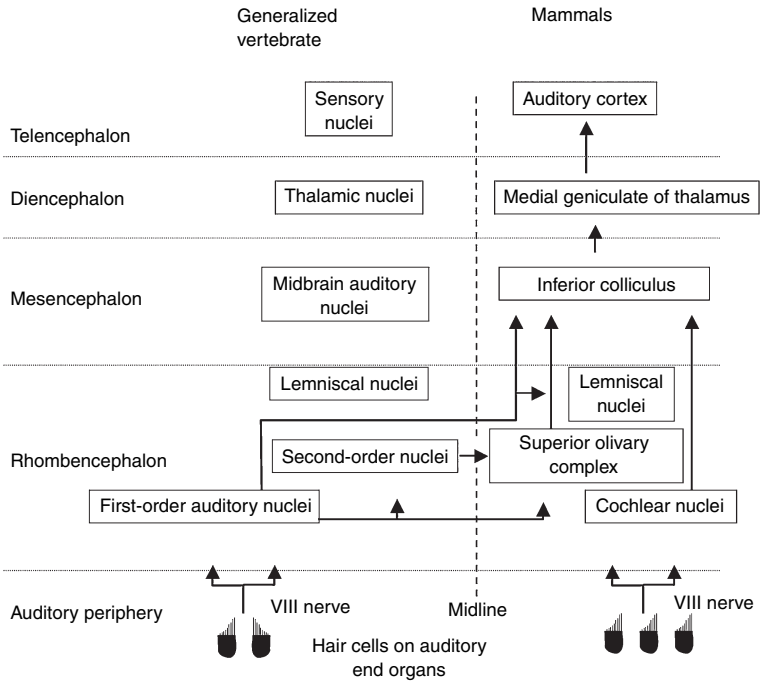

Figure 1 Simplified ascending auditory pathway in vertebrates. A generalized pathway common to all vertebrates is shown on the left, with the mammalian pathway compared on the right. Note that not all components are shown (see text).

relay excitatory information to the afferent neuron. Stimulation at angles in between these two results in a graded response that reflects how close the stimulus axis is to the best axis. Therefore, the surface structures of the hair cell can impart both frequency sensitivity and directional sensitivity to the ear, both of which can be used to encode specific attributes of a sound source to the central nervous system.

The auditory system takes many forms among the vertebrates. Some vertebrates have outer ears, but many do not. The outer ear may consist of paired pinnae (mammals), membrane-covered openings, or simply an opening on both sides of the skull that leads to a middle ear (some amphibians and Sphenodon). Fishes lack an outer ear and do not have a true middle ear. Hair cells are found in the inner ear, which is also quite variable when viewed across the vertebrates. There are two components within the ear of all vertebrates that serve different purposes. Vestibular structures encode tilt and angular motion, providing information about orientation and movement with respect to gravity. Auditory structures encode the particle motion associated with sound. The task of encoding sound may be done by multiple end organs, which usually have parceled out sound detection by frequency or sensitivity. In other words, two end organs may have hair cells that respond to similar frequencies, but the sounds may be encoded differently in the afferent neurons that send the information to the brain (e.g., with broader frequency responses or only at higher sound levels). Thus, in fishes, there can be three or four end organs that encode sound, and in mammals there are at most two, with the second playing a very limited role in auditory processing, and which may be a remnant of the ancestral inner ear.

3.30.1.2 Overview of General Auditory Pathway for All Vertebrates

The organization of the central auditory system is similar among all vertebrates with functional ears (Figure 1). Despite the similarities, it is not clear whether the components of the central auditory system are homologous, or whether the evolution of the central auditory system merely follows the organizational pattern common to the octaval system (Grothe, B. *et al.*, 2004). Evolutionary changes in the peripheral auditory end organs, combined with a lack of detailed embryological studies on the origins of the central auditory cells, are the basis for the present uncertainty in determining homologies in the central auditory system.

The auditory nerve projects to a column of first-order auditory nuclei, also termed cochlear nuclei in birds and mammals (Table 1). These projections are tonotopically organized, when tonotopic organization

Table 1 Comparison of hindbrain components along the auditory pathway in vertebrates

is found in the periphery. The projections to different first-order nuclei mediate the emergence of coding for different aspects of the auditory stimulus, such as sound timing and level. Furthermore, the first-order nucleus projections contribute to two ascending streams, one binaural, combining information from the two ears, and the other monaural. The binaural stream is formed when projections from the ipsilateral and contralateral nuclei converge on second-order hindbrain nuclei that project in parallel with the monaural nuclei to the midbrain. The auditory brainstem shows substantial anatomical diversity between the major vertebrate taxa (reviews in Cant, N. B., 1992; McCormick, C. A., 1998; Carr, C. E. and Code, R. A., 2000; Grothe, B. *et al*., 2004). The auditory midbrain receives ascending inputs from both monaural and binaural hindbrain nuclei, and physiological recordings have revealed the emergence of complex response properties there. The midbrain projects to the thalamus, which in turn projects to auditory stations in the telencephalon. The organization of the telencephalon is structurally and functionally diverse. In all vertebrate clades (monophyletic groups of organisms), the telencephalon exhibits large changes associated with the increased use of sound for communication. Finally, in addition to these ascending pathways, the central auditory system is characterized by multiple descending projections.

3.30.2 Functional Organization in Fishes

In this chapter, we will use the term fishes to include only the jawed fishes, that is, the Chondrichthyes and Osteichthyes. We will not include the jawless Agnatha (lampreys and hagfish) in this review since there is nothing known about auditory processing in those fishes. (However, it is important to note that they have hair cells on end organs that may function in audition.) The Chondrichthyes include the sharks, skates, and rays. The Osteichthyes (bony fishes) include primitive fishes and modern fishes commonly called teleosts.

Sound may reach the inner ear of bony fishes in two ways. The most common pathway is directly through the fish's body to the auditory end organs. The compressions and rarefactions of the water medium cause particle motion that is easily transmitted through the fish's soft tissues due to the similarity in the density of water and tissue. The second pathway, called the indirect pathway, utilizes the presence of an air-filled structure (gas bladder or special otic sac) that is mechanically coupled in some way to the fluids surrounding the auditory end organs. The pressure component of sound causes the air-filled structure to expand and contract, thus producing particle motion

that is transmitted to the ear via the mechanical connection. The indirect pathway is found in a group of fishes called the otophysines (most of which are freshwater species), weakly electric fishes (mormyrids), and herrings. The presence of this second pathway is correlated with greater sensitivity to higher frequencies (>1 kHz) than is found among fish species that have only the direct pathway and hear best below about 500 Hz. There is controversy at present as to whether the indirect pathway can function in fishes that have a gas bladder but lack a mechanical link to the inner ear, since the tissues between the gas bladder and the ear may conduct particle motion (see discussion by Popper, A. N. *et al.*, 2003 and Chapter Underwater Hearing). This indirect pathway does not exist in cartilaginous fishes because they do not have gas bladders.

The majority of the data on the sense of hearing in fishes has been collected from teleosts (Fay, R. R. and Simmons, A. M., 1999; Popper, A. N. *et al.*, 2003), and we will focus on their ascending auditory pathway, with less attention to the cartilaginous and primitive fishes. In addition, there are reciprocal connections between auditory nuclei and descending projections to auditory and nonauditory nuclei at different levels of the pathway, which are not well documented in many fish species, and for simplicity, will not be discussed here. The reader interested in more detailed information about the auditory pathways in cartilaginous and primitive fishes is encouraged to refer to McCormick C. A. (1999) for a comparison of central auditory pathways among all fishes.

3.30.2.1 The Auditory Periphery of Fishes

The auditory periphery refers to the components of the auditory system that are not part of the central nervous system. The periphery of the auditory system of all vertebrates includes the auditory end organs with their sensory hair cells (Figure 2(a)) and the afferents in the acoustic cranial nerve (VIII) that innervate the hair cells and project to auditory processing areas in the medulla. In fishes more than any other vertebrate, the variation in the morphology and orientations of sensory hair cells in the ear have the capability of encoding the axis of stimulation. For that reason, we will provide some background information about hair cells that is pertinent for the discussion of fish auditory circuitry that follows.

The sensory hair cells in the ears of fishes have the stair-step array of stereovillae that is present on the hair cells of all vertebrates (see Chapter Phylogeny and Evolution of Ciliated Mechano-Receptor Cells). In addition, each hair cell has a single kinocilium. The most excitatory direction for a hair cell is along the axis that points from the shortest row of stereovillae to the kinocilium (Figure 2(a)). In all vertebrates, the hair cells are organized on auditory epithelia in specific ways that are predictable within a given species. There is much variety in hair cell orientation among the auditory end organs of different teleosts (Popper, A. N. and Coombs, S., 1982). Their most important feature is that the variety in hair cell orientations on the auditory end organs of fishes provides the ear with the ability to respond to sounds originating from different directions and also provides the potential for relaying that directional information to the brain.

There are four potential auditory end organs in the ears of fishes: the macula neglecta, saccule, lagena, and utricle. The macula neglecta (sometimes called the papilla neglecta) differs in two major ways from the other three end organs. First, the hair cells of the macula neglecta are in contact with a gelatinous cupula; the hair cells of the saccule, lagena, and utricle are associated with an otolith. Second, the hair cells of the macula neglecta are oriented in various directions, with best directions often organized radially from the center of the epithelium. The hair cells on the saccule, lagena, and utricle are oriented in various directions as well, but in nearly all cases, each hair cell has a 180° counterpart.

The detection of hair cell motion in the ear depends on both the frequency and amplitude (level or loudness) of the stimulus. The effective stimulus can be very low frequency (e.g., $<1\,\mathrm{Hz\,s^{-1}}$), as in linear acceleration or tilt of the head, or may consist of higher frequencies, such as environmental sounds. Hair cells with very different frequency sensitivities may be mixed on the same epithelium in the ear (e.g., vestibular vs. auditory). Therefore, the sensory role for any end organ in the ear of fishes cannot be assumed – physiological investigations are needed to confirm the range of response characteristics, although the organization of sensory afferent projections to the brain provides useful clues. In this section, we will base our descriptions of auditory pathways in fishes on comparative anatomy as well as physiological investigations.

The macula neglecta appears to be the primary auditory end organ among sharks (Corwin, J. T., 1989). The size of this end organ varies among shark species and its role in hearing may vary as well. In an adult Carcharhinid shark, the macula is composed of two patches, containing about 200 000 hair cells that project to about 4700 myelinated nerve

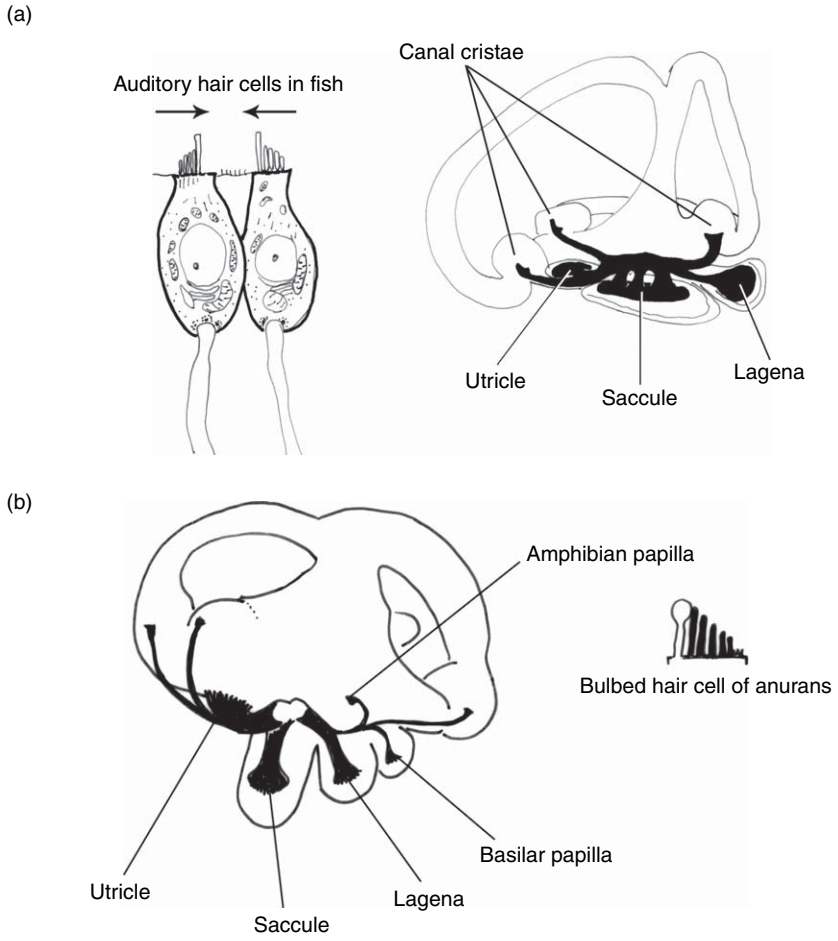

Figure 2 Illustrations of anamniote inner ears, medial view. The sensory end organs and the branches of VIII are shown in black. (a) Generalized teleost fish. Note that the hair cells on each of the sensory epithelia occur in opposing orientations (arrows indicate best directions for the two hair cells shown; they are separated by a support cell). Hair cells of fishes have both a kinocilium (white) and stair-step arrays of stereovillae (black). The semicircular canal cristae are included for completeness, but are not auditory structures. (b) Generalized anuran ear. The hair cells are oriented in various patterns, as in fishes, but a unique hair cell, with a bulbed kinocilium occurs in anurans. Note the relative sizes and locations of the amphibian papilla and basilar papilla. Adapted from Lewis, E. R., Leverenz, E. L., and Bialek, W. S. 1985. The Vertebrate Inner Ear. CRC Press, figures 4 and 8; and Will, U. and Fritzsch, B. 1988. The Eighth Nerve of Amphibians: Peripheral and Central Distribution. In: The Evolution of the Amphibian Auditory System (*eds*. B. Fritzsch, M. J. Ryan, W. Wilczynski, T. E. Hetherington, and W. Walkowiak), pp. 159–183. Wiley, figure 1.

fibers (Corwin, J. T., 1977). Some teleost fishes have a macula neglecta, but in general, the end organ is very small, and its function has not been determined physiologically in any teleost.

The paired saccules are the most common otolithic end organ associated with hearing in fishes. The hair cells have a variety of apical bundle morphologies, including differences in the relative height of the kinocilium versus the stereovillae (Platt, C. and Popper, A. N., 1981; 1984), that no doubt influence the response characteristics (Chapter Mechano-Acoustical Transformations). Most of the work on auditory responses of the saccule have been conducted in teleost fishes (Fay, R. R. and Simmons, A. M., 1999), but an auditory function for the saccule was demonstrated in the lemon shark, *Negaprion brevirostris*, by Corwin J. T. (1981). Lowenstein O. and Roberts T. D. M. (1951) estimated that two-thirds of the saccule in some sharks, skates, and rays respond to sound vibrations. The remaining portion of the saccule responds to tilt.

The lagena is intriguing due to the apparent flexibility in both the structure and function of this end organ. In sharks, skates, and rays, the lagena, in addition to a portion of the saccule, may be sensitive to

tilt. In bony fishes, the lagena may respond to vibration for auditory processing (e.g., goldfish, Fay, R. R., 1984; and freshwater goby, Lu, Z. *et al.*, 2003) and/or respond to tilt for vestibular processing (e.g., toadfish, Locke, R. *et al.*, 1999). Lu Z. *et al.* (2003) have suggested that the lagena may be important for extending the dynamic range of the auditory system in teleost fishes, since it is less sensitive to auditory frequencies than the saccule in the sleeper goby. There are no data indicating the presence (or absence) of a frequency map on the lagena in species for which auditory responses have been documented, although Platt C. (1977) documented considerable variation in apical bundle morphology on the goldfish lagena.

In most fishes, the utricle is very similar in appearance to the utricle of other vertebrates. The utricle is assumed to play a major role in encoding linear acceleration in the horizontal plane. However, Lowenstein O. and Roberts T. D. M. (1951) found that although most of the utricle of a skate (*Raja clavata*) responds to tilt, a small portion responds to vibration. There is evidence that the utricle could respond to higher frequencies and contribute to directional hearing (Fay, R. R., 1984; Lu, Z. *et al.*, 2004). Tomchik S. M. and Lu Z. (2005) presented strong anatomical evidence for a mixture of vestibular and auditory functions in the utricle based on the interdigitation of utricular afferents with those of the other two otolith organs in the dorsal medulla and with the semicircular canal cristae projections in the ventral medulla of the sleeper goby. In addition, Wallace A. C. and McCormick C. A. (2005) showed utricular and saccular afferents terminating on the same cells in the descending octaval nucleus (see below). In some teleost fishes, the utricle has a very different morphology with distinct subdivisions of the macula. In at least one herring species, one of the utricular subdivisions clearly functions in auditory processing (Denton, E. J. *et al.*, 1979; Mann, D. A. *et al.*, 2001).

The diversity of response characteristics for the end organs in the ear of fishes makes generalizations about the auditory periphery among fishes difficult. The best data are from species for which both auditory physiology and neuroanatomical analyses have been conducted. In the next section, we will discuss the organization of auditory inputs from the ear to the medulla, based on anatomical data from species for which the peripheral auditory end organs have been identified.

3.30.2.2 The Auditory Medulla in Fishes

Primary afferents innervating the end organs with auditory responses may send their axons to one or more nuclei in the medulla. Four nuclei are arranged rostrocaudally in the octaval column in the medulla of cartilaginous and primitive bony fishes: anterior, descending, magnocellular, and posterior. In teleost fishes, the octaval column has an additional nucleus, the tangential nucleus. Of these nuclei in the octaval column, only the anterior (AON) and/or descending (DON) octaval nuclei have ascending projections to the auditory midbrain. Although the magnocellular and tangential octaval nuclei may also be involved in directional responses to sound, in that they have been implicated in coordinating reflex responses to sound via the spinal cord (Highstein, S. M. *et al.*, 1992; Puzdrowski, R. L. and Leonard, R. B., 1993; Suwa, H. *et al.*, 1999), there is no evidence that either nucleus is a component of the ascending auditory circuit.

All of the octaval nuclei appear to receive a mixture of inputs from multiple end organs. Auditory inputs tend to be more dorsal and extend more medially than vestibular inputs in the anterior and descending nuclei in both cartilaginous and bony fish species for which inner ear projections have been examined in detail (McCormick, C. A., 1992; 1999). Similarly, the subset of cells in these first-order nuclei that project to higher-order auditory nuclei are located in the more medial zones of the anterior and descending nuclei (Figure 1, Table 1).

One study has characterized the auditory responses of single primary saccular afferents in the toadfish and revealed their central projections with intracellular injections of neurobiotin (Edds-Walton, P. L. *et al.*, 1999). Some, though not all, saccular afferents bifurcated upon entering the medulla. The rostral branch of the axon projected to the AON, and the caudal branch projected to the dorsal zones of the DON. Each branch tended to have multiple termination sites in each nucleus, although cells in the DON received the greatest proportion of inputs from the bifurcating saccular fibers. The distribution of the auditory inputs to those nuclei was distinctively different, however. Projections into the AON were radially organized. Projections into the DON tended to extend rostrocaudally with multiple synaptic sites at intervals down the length of this elongate nucleus. The functional significance of that organization is not yet known. Given that most saccular afferents are broadly tuned with overlapping response areas, as is the case in all fishes for which such data are available

(Fay, R. R. and Simmons, A. M., 1999), a tonotopic organization is unlikely.

No studies have documented the range of response properties of first-order auditory nuclei in cartilaginous fishes or primitive fishes, and only a few studies have been done in teleost fishes. Some of these studies have been carried out on teleosts that vocalize, including toadfish, midshipmen, and mormyrid fishes. Phase-locking is characteristic of the majority of auditory cells in the medulla of fishes (see discussion in Feng, A. S. and Schellart, N. A. M., 1999). In the weakly electric mormyrid fishes, *Pollimyrus* sp. evidence was presented for both frequency and timing computations in the medulla that might contribute to conspecific call recognition (Kozloski, J. and Crawford, J. D., 1998). In the toadfish, recordings from identified sites in the DON revealed more specific frequency and directional responses than found in the nerve (Edds-Walton, P. L. and Fay, R. R., 2005b).

The requirements of directional hearing might be reflected in the organization of the DON. Binaural interactions can occur at this level of the auditory circuit of fishes in two ways. First, in some fishes, a subset of afferents from the auditory end organ(s) projects to a dorsomedial zone of both the ipsilateral and contralateral DONs (McCormick, C. A., 1992; 1999). Second, in some teleosts, cells in the DON have reciprocal connections with cells in the contralateral DON (Nieuwenhuys, R. and Pouwels, E., 1983; Edds-Walton, P. L., 1998; Tomchik, S. M. and Lu, Z., 2005). The reciprocal connections provide the potential for left–right comparisons for directional computations. Alternatively, the binaural interactions may be part of a common mode rejection circuit to eliminate self-generated noise (Duman, C. H. and Bodznick, D., 1996; 1997). At present no physiological studies have documented the response properties of binaurally driven cells in the DON. However, binaurally driven cells have been found in undocumented sites in the medulla of the cod (Horner, K. *et al.*, 1980).

Another potential site for binaural interactions in the medulla is among cells in the secondary octaval population (SOP). There are a minimum of two divisions of secondary octaval cells usually located in the rostral medulla, near the entrance of eighth nerve. The two divisions are (1) a dorsal grouping of cells lying near the ventricle and (2) a ventral grouping located more medially and often near the internal arcuate tract. A third division, consisting of spherical cells that lie intermediate to the dorsal and ventral divisions, has been described for the goldfish (McCormick, C. A. and Hernandez, D. V., 1996), but the intermediate division may not be present in all teleosts (McCormick, C. A., 1999). In addition, a primitive fish, the bowfin (*Amia calva*) has only the ventral division (McCormick, C. A. and Braford, M. R., Jr., 1988), suggesting that a single ventral nucleus may be the primitive vertebrate condition.

The sources of inputs to the SOP are not known with any certainty. The cells of the dorsal division have a ventral process that extends into the more dorsal and medial regions of the DON (where saccular input is also found) and a dorsal process that traverses the lateral line nucleus medialis and enters the cerebellar crest (McCormick, C. A., 1999). Therefore, the dorsal division could be integrating primary saccular input, DON cell input, and medialis input, with modulation from the cerebellum. McCormick C. A. (1999) suggests that the ventral and intermediate divisions of the SOP may be components of a descending acoustic pathway since those divisions receive input from the auditory midbrain in goldfish. At present there is no evidence to suggest that any division of the SOP is homologous to the superior olivary nuclei of tetrapods.

The pathway from the medulla to the auditory midbrain is the same in fishes as in other vertebrates. Projections from the first- and second-order auditory nuclei ascend via the lateral lemniscus. There is also some evidence for an intermediate nucleus (e.g., paralemniscal nucleus or nucleus of the lateral lemniscus) that may act as a relay for some of the projections to the auditory midbrain (McCormick, C. A., 1999; Edds-Walton, P. L. and Fay, R. R., 2005a).

3.30.2.3 The Auditory Midbrain of Fishes

The midbrain is a major site of convergence for the many sensory systems found among fishes: vision, audition, lateral line, and the electric sense. The lateral mesencephalic complex (LMC) in the midbrain of cartilaginous fishes can be subdivided into as many as four nuclei in some species (e.g., skates and rays), but the identification of a discrete auditory nucleus has proved elusive, particularly in sharks, likely due to a substantial amount of sensory integration. The strongest evidence indicates that the medioventral nucleus of the LMC can be an auditory center (e.g., Barry, M. A., 1987). In bony fishes, a physiologically and anatomically distinctive auditory region (nucleus centralis) is usually dorsal to, and sometimes medial to, the lateral line nucleus (nucleus

ventrolateralis or n. ventralis) in the torus semicircularis (torus) of the midbrain (see figure 17.11 in McCormick, C. A., 1992). In electroreceptive fishes, the auditory nucleus may be sandwiched between the electrosensory nucleus and the lateral line nucleus, but in another variation, the lateral line and auditory inputs may converge (in the mediodorsal nucleus), as demonstrated in a weakly electric fish (Crawford, J. D., 1993).

Spontaneous activity and phase-locking are reduced in the midbrain compared to primary afferents (summarized by Feng, A. S. and Schellart, N. A. M., 1999). Two studies have been conducted similarly and provide comparable data. In the goldfish torus, Lu Z. and Fay R. R. (1993) found cells with either no spontaneous activity or activity below 20 spikes s^{-1}. Cells in the toadfish torus also had a similar range of activity, with most below 5 spikes s^{-1} (Edds-Walton, P. L. and Fay, R. R., 2003). Phase-locking is present among a subset of cells in the auditory torus, though there are no data to indicate that they are located in a particular functional subunit of the torus.

Auditory recordings in the torus provide evidence for additional computations along the auditory pathway or within the torus that produce cells with unique frequency response areas (compared to saccular inputs) and cells with sharpened directional responses (Lu, Z. and Fay, R. R., 1993; Ma, W. L. and Fay, R. R., 2002; Edds-Walton, P. L. and Fay, R. R., 2003; Edds-Walton, P. L. and Fay, R. R., 2005b). Edds-Walton P. L. and Fay R. R. (2003) compared frequency tuning with directional sharpening and found that the computations are independent. In other words, a directionally sharpened cell in the torus is not necessarily highly tuned.

Bimodal sites have been documented in the midbrain of fishes by several investigators, however, no functional neuroanatomy has been conducted in the midbrain of fishes using all potential stimuli to sort out multimodal sites. As McCormick C. A. (1999) notes, the presence of a nucleus that receives input predominantly from one sensory pathway does not preclude the presence of multimodal cells or areas. Bimodal auditory and visual (AV) cells were found in the tegmentum, deep to the torus of goldfish (Page, C. H. and Sutterlin, A. M., 1970) and the trout (Schellart, N. A. M., 1983; Schellart, N. A. M. and Kroese, A. B. A., 1989). Schellart N. A. M. *et al.* (1987) also found a vertical gradation in relative responsiveness to auditory versus visual stimulation, with unimodal cells tending to lie at the extremes (auditory most dorsal, visual most ventral).

Bimodal auditory and lateral line cells were found throughout the torus of the toadfish (Edds-Walton, P. L. and Fay, R. R., 2003). Neurobiotin injections at sites with auditory and lateral line bimodality revealed multipolar cells with processes that extended throughout both subdivisions of the torus. In addition, retrogradely filled input cells indicated that bimodality was the result of convergence of inputs from medullary auditory and lateral line cells rather than interconnections between lateral line responsive cells in nucleus ventrolateralis and auditory cells in nucleus centralis (Edds-Walton, P. L. and Fay, R. R., 2005a). Finally, Edds-Walton P. L. and Fay R. R. (2003) presented physiological data that indicated a dorsal–ventral gradation in relative responsiveness to auditory versus lateral line stimulation. As was found with auditory and vestibular cells in trout, auditory and lateral line-responsive cells in toadfish tended to be more common at intermediate depths, and auditory-only cells tended to be located most dorsally in the torus.

The data on unimodal versus bimodal cells in the torus reflect sensory mapping across sensory modalities; however, maps within a sensory modality, such as audition, have not been well demonstrated in fishes. Tonotopy may be present in a relatively gross way, but there are no data to indicate a strict tonotopic organization in the auditory torus. In several physiological surveys of the torus, more cells with high best frequencies were found in the rostral torus than in the caudal torus (carp, *Cyprinus carpio*, Echteler, S. M., 1985; rainbow trout, *Oncorhynchus mykiss*, Schellart, N. A. M. *et al.*, 1987; toadfish, *Opsanus tau*, Edds-Walton, P. L. and Fay, R. R., 2003).

Only one study has provided evidence for a spatial auditory map in a trout, based on directional stimuli in the horizontal plane (Wubbels, R. J. *et al.*, 1995). Furthermore, these authors suggested a columnar organization in the torus based on similar response characteristics among consecutive recording sites along vertical tracts. Another study in toadfish, using horizontal and vertical plane directional stimuli, did not reveal a simple spatial auditory map in the toadfish nucleus centralis (Edds-Walton, P. L. and Fay, R. R., 2003).

In summary, the midbrain of cartilaginous and bony fishes is not easily separated into functional neuroanatomical units. In teleosts, there is mounting evidence that multimodal cells are not strictly segregated from unimodal cells in the midbrain, and there is considerable variety in midbrain organization. The amount of overlap among sensory systems in the

midbrain may be species dependent and may reflect species-typical requirements for emphasizing particular aspects of the sensory experience (Feng, A. S. and Schellart, N. A. M., 1999).

3.30.2.4 The Auditory Forebrain of Fishes

The forebrain includes the diencephalon and telencephalon; both will be discussed in this section. Auditory components have been identified from tract-tracing studies, but much remains to be learned about auditory processing in the forebrain. We will focus on what is known about the ascending projections to the diencephalon and telencephalon. More detailed discussions are available in Braford M. R., Jr. (1995), Striedter G. F. (1997), and Northcutt R .G. (2006).

The auditory torus projects to the central posterior nucleus of the dorsal thalamus in all fishes examined to date and the ventromedial nucleus of the ventral thalamus in some species (see McCormick, C. A., 1999). Lu Z. and Fay R. R. (1995) confirmed the presence of auditory responses in the central posterior nucleus in goldfish, though their data indicated less auditory specificity (broader frequency tuning and less phase-locking) than previously recorded in the goldfish midbrain. Projections from the midbrain have also been noted in the anterior tuberal nucleus of the hypothalamus, with reciprocal connections noted in some species (reviewed in McCormick, C. A., 1999; Northcutt, R. G., 2006).

The lateral preglomerular complex of the diencephalon is a recipient of midbrain projections that are likely to have auditory components (McCormick, C. A., 1999). Auditory inputs have been revealed in goldfish: the auditory torus projects to the caudal subnucleus of the lateral preglomerular complex, while the rostral subnucleus of the lateral preglomerular nucleus receives input from the medial pretoral nucleus (Northcutt, R. G., 2006). The medial pretoral nucleus is found in the midbrain of otophysines (no other teleost groups to date) and receives inputs from the auditory torus. Therefore, in otophysines, there may be an additional auditory pathway from the midbrain to the diencephalon. This is of special interest due to the potential for parallel processing of pressure versus particle motion components of sound that may be used for directional hearing (Fay, R. R., 2005).

The auditory pathway culminates in the dorsal region of the telencephalon. Within the dorsal telencephalon, two pallial divisions, medial (Dm) and lateral (Dl), receive auditory input either from ascending pathways or intrinsic connections. The relative contributions of ascending auditory input from dorsal thalamus versus the preglomerular complex may vary among fish species (see discussion in Northcutt, R. G., 2006); however, what constitutes the thalamus in teleosts remains an issue. Projections to the pallium are believed to originate in the central posterior nucleus and/or the anterior nucleus of the dorsal thalamus. The rostral subnucleus of the lateral preglomerular nucleus projects to both Dm and Dl; the caudal subnucleus of the lateral preglomerular complex and the anterior preglomerular nucleus project only to Dm. Braford M. R., Jr. (1995) and Northcutt R. G. (2006) have argued that much of the dorsal telencephalon in goldfish and other teleosts may be more limbic than isocortical in organization.

Physiological studies have revealed both unimodal and multimodal sites in the telencephalon. An investigation using four different sensory stimuli (auditory, visual, electrosensory, and lateral line) and electrode arrays found that most sites in the Dm of a weakly electric fish were unimodal (Prechtl, J. C. *et al.*, 1998). The comparatively rare bimodal or multimodal sites were clustered at the borders of unimodal sites in Dm. Included among the bimodal loci were auditory-lateral line and auditory-electrosensory sites. Clearly, more data are needed before we can begin to understand sensory processing in the telencephalon. Physiological studies of diencephalic/telencephalic sites in representatives of the major groups of fishes could provide much needed insights into the functional organization of the auditory pathway.

3.30.3 Functional Organization in Lissamphibians

There are three major radiations of lissamphibians (extant amphibians): the frogs and toads (Anura), the salamanders and aquatic newts (Urodeles or Caudata), and the limbless caecilians (Gymnophiona). There is considerable diversity in the structures involved in transducing sound from the environment to the inner ear (e.g., presence or absence of a tympanum) and in the role of hearing in the behavioral ecology of lissamphibia, which we cannot cover here. Several recent publications provide excellent reviews of the diversity of auditory systems and hearing among the amphibians (e.g., Fritzsch, B. *et al.*, 1988; Fay, R. R. and Simmons, A. M., 1999; Lewis, E. R. and Narins, P. M., 1998; Smotherman, M. and Narins, P. M., 2004; Rose, G. J.

and Gooler, D. M., 2007). There are also interesting variations in the ways that sound reaches the fluid-filled inner ear among the lissamphibia that cannot be described here. For a detailed discussion about the columellar subsystem (for underwater and airborne sound) and the opercular subsystem (for substrate vibrations) of anurans, see Lewis E. R. and Narins P. M. (1998) and Mason M. J. (2007).

Frogs have garnered most of the attention of research scientists interested in amphibian hearing. Most anurans are vocal, providing the experimenter with an obvious starting point in determining the types of sounds most likely to be encoded by the auditory system. Far less is known about auditory processing in salamanders, newts, and caecilians, and they will not be described here.

3.30.3.1 The Auditory Periphery of Lissamphibians

Diversity in the range of auditory end organs is arguably the greatest among the lissamphibians. Lissamphibian auditory end organs include some of those present in fishes, plus two end organs not found in any teleost fish, though there may be an homologous structure in an ancient fish (see Fritzsch, B., 1992). In addition, the hair cells of most anurans have a unique kinocilium with a bulbed tip (Figure 2(b)).

The auditory end organs that amphibians have in common with fishes are the lagena and saccule. Hair cells are oriented in specific patterns on those end organs as in fishes. Unlike those end organs in teleost fishes, there is not a single dense otolith, but rather an otoconia (a suspension of calcareous particles) associated with a gelatinous matrix that contacts the apical structures of the hair cells. The lagena appears to be a mixed auditory/vestibular end organ in at least some of the anurans, with sensitivity to low-frequency vibration and sensitivity to linear acceleration (posture) in different regions of the lagena (Cortopassi, K. A. and Lewis, E. R., 1995; 1996). There is no evidence for mixed vestibular and auditory function in the amphibian saccule. The saccule and the lagena encode the lowest frequencies, including substrate vibrations from predators or prey. In some burrowing anurans, the saccule may also be part of the auditory circuit that encodes calls transmitted through the substrate. The utricle, which has auditory sensitivity in some teleost fishes, is believed to be sensitive only to head movements and not to vibration in lissamphibians.

The two additional auditory epithelia found among the lissamphibians are the low-frequency sensitive amphibian papilla and the higher-frequency sensitive basilar papilla. The amphibian papilla is found in all lissamphibians; the basilar papilla is present in most of the lissamphibians. The sensory hair cells are oriented in characteristic patterns along these papilla, with systematic variations in surface morphology (e.g., relative height of kinocilium vs. stereovillae). Associated with the surface of the hair cells on the amphibian and basilar papillae is a gelatinous structure called a tectorium or tectorial membrane. The tectorium of the amphibian papilla varies in relative thickness, which, in addition to variations in hair cell morphologies, has been correlated with the tonotopic map common along that end organ (Shofner, W. P., 1988). The tectorium of the basilar papilla varies among amphibian groups, having greatest complexity in the anurans (Lewis, E. R. and Narins, P. M., 1998). Both the amphibian and basilar papilla vary in relative size among amphibians. The amphibian papilla is usually the largest end organ, and its size is associated with the frequency response. The larger the amphibian papilla, the broader the frequency response for that end organ, with the range extended to higher frequencies rather than lower. Hair cells with shorter ciliary bundles and higher-frequency responses are found most caudally. Although there are systematic variations in hair cell morphologies, there is no evidence for tonotopy on the basilar papilla.

Lewis E. R. and Narins P. M. (1999) note that frequency sensitivity seems to be distributed among the different end organs in a systematic way: the saccule encodes the lowest frequencies (<100 Hz), the amphibian papilla encodes intermediate frequencies (around 80–1000 Hz), and the basilar papilla encodes the highest frequencies (around 1–4 kHz). They also state that in all species studied thus far, the basilar papilla encodes some component in the species' vocalizations. The amphibian papilla may also respond to lower-frequency components of a conspecific call.

In general, auditory afferents have low spontaneous activity (0–80 spikes s^{-1}), have fairly distinct best frequencies, and phase-lock well up to about 1 kHz (Christensen-Dalsgaard, J. *et al.*, 1998; Lewis, E. R. and Narins, P. M., 1998). However, the higher-frequency fibers from the basilar papilla do not exhibit good phase-locking and are more broadly tuned than the fibers from the amphibian papilla. Zakon H. H. and Wilczynski W. (1988) suggested that the combined output of the two end organs may be critical for recognition of communication signals

that sweep through a wide range of frequencies (frequency-modulated or FM signals).

3.30.3.2 The Auditory Medulla of Amphibians

The majority of the work on amphibian auditory physiology and anatomy has been conducted on frogs or salamanders. Comparisons of the ascending auditory systems can be found in Will U. and Fritzsch B. (1988) and McCormick C. A. (1999). Here we present a general summary with highlights of some of the differences between anuran and nonanuran amphibians.

Input from the peripheral auditory end organs enters the medulla via the anterior and posterior rami of VIII. The fibers from the amphibian and basilar papillae travel in the posterior ramus with lagenar fibers (Figure 2(b)). Saccular fibers may travel in either the anterior or posterior ramus. All auditory fibers bifurcate as they enter the medulla, resulting in ascending tracts to the primary auditory nuclei and cerebellum and descending octaval tracts to the region of the obex (Will, U. and Fritzsch, B., 1988). The organization of the medulla varies depending on the presence of a lateral line system. When a lateral line region is present in larval amphibians and the aquatic urodeles, inputs to the auditory medulla are located more laterally and ventrally (see figure 3 in Will, U. and Fritzsch, B., 1988). Among octaval inputs, the auditory processing regions tend to be more dorsal than the vestibular sites.

The acoustic region in the medulla among urodeles and caecilians is more diffuse than in anurans (McCormick, C. A., 1999) and there is much overlap in the projections of the auditory end organs. The region of the medulla that receives octaval inputs in nonanurans is designated as the ventral zone. The anurans have a similarly organized ventral zone, but also have a well-defined auditory nucleus that lies dorsal to the ventral zone, the dorsal medullary nucleus (DMN, Feng, A. S. and Capranica, R. R., 1976; Feng, A. S., 1986; also called the dorsal lateral nucleus or the dorsal nucleus; see Table 1).

Afferents from the lagena and the saccule project to the ventral zone in both nonanurans and anurans. We have noted earlier that a region of the lagena and the entire saccule respond to low-frequency, vibrational stimuli. In addition, both lagenar and saccular inputs overlap with inputs from the canal cristae and the utricle in other octaval projection sites in the medulla. This region has not been well characterized physiologically, but the distribution of input is consistent with the fact that the majority of the hair cells in the lagena are vestibular. The functional significance of the saccular overlap is less clear, since there is no evidence for vestibular responses among saccular afferents. Cells of the ventral zone project down the spinal cord in the vestibulospinal tract (Will, U., 1988), and thus, the saccular input could be involved in a reflex orientation circuit that coordinates responses to seismic stimuli (e.g., predator movements). In addition, saccular afferents also project to the nucleus saccularis of Matesz (see McCormick, C. A., 1999), which does not receive inputs from the amphibian and basilar papillae. The distribution of saccular inputs among octaval sites in the medulla is intriguing and may be a function of the behavioral significance of low-frequency, seismic stimuli to the species under consideration.

Inputs from the amphibian papilla and the basilar papilla are organized tonotopically in the ventral zone in both anurans and nonanurans and in the DMN in anurans. Saccular afferent inputs are generally most ventral in the ventral zone in nonanurans and are not intermingled with amphibian and basilar papilla inputs in the DMN of anurans. Response characteristics of DMN cells are similar to those of primary auditory afferents in about half the cells, but new firing patterns also emerge, for example, onset-only and phasic bursting cells (discussed in more detail in Feng, A. S. and Schellart, N. A. M., 1999). Phase-locking to tones is poor among those cells, and their frequency responses are relatively low. Feng A. S. and Schellart N. A. M. (1999) suggest that these DMN cells are most important for encoding temporal patterns.

A commissural tract exists between the two DMN, making this the first site along the auditory pathway in which binaural interactions occur (Feng, A. S. and Capranica, R. R., 1976; Christensen-Dalsgaard, J. and Kanneworff, M., 2005). Feng A. S. and Capranica R. R. (1976) presented anatomical and physiological evidence that the commissural connections are homotopic, and that a proportion of the binaural cells are sensitive to interaural time differences (ITDs). Other interconnections exist among primary octaval regions of the medulla and the cerebellum that we will not discuss as their role in auditory processing is unknown. None of those areas project to the auditory midbrain.

Among amphibians, only anurans have a secondary acoustic nucleus in the ventral medulla, called the superior olivary (SO) nucleus. The SO of anurans is a single nucleus (not a complex as found in teleosts or

mammals) that receives bilateral input from the DMN and from a portion of the ventral zone that has inputs from all four auditory end organs. Contralateral inputs tend to predominate. The inputs are organized both tonotopically and by laterality: the ipsilateral DMN inputs terminate more ventrally than the contralateral DMN inputs (Will, U., 1988). Sensitivity to temporal characteristics of stimuli is retained among cells in the SO (Walkowiak, W., 1988), and the range of firing patterns recorded in the DMN are also present in the SO (Condon, C. J. *et al.*, 1995). However, additional frequency, amplitude modulation, and temporal encoding are evident as more specific combinations of these features are required by some cells (described in detail by Feng, A. S. and Schellart, N. A. M., 1999).

Auditory projections ascend to the midbrain in the lateral lemniscus in amphibians, as in all vertebrates. Wilczynski W. (1988) and McCormick C. A. (1999) have suggested that a nucleus found in close proximity to the lateral lemniscus may have a role similar to the nucleus of the lateral lemniscus in other tetrapods, which is also supported by some physiological work (Rose, G. J. and Wilczynski, W., 1984). Since the relationship of this nucleus to the lemniscal nuclei of other tetrapods is unclear, it is referred to as the superficial reticular nucleus by McCormick C. A. (1999), as a portion of the nucleus lies just lateral to the reticular formation. The superficial reticular nucleus receives input from the ipsilateral superior olive and also direct input from the contralateral DMN.

3.30.3.3 The Auditory Midbrain of Anurans

The auditory midbrain of amphibians, the torus semicircularis (torus), is considered to be homologous to the auditory midbrains of tetrapods. Our examination of the auditory pathway through the midbrain will be restricted to that of anurans due to a paucity of information on urodeles and caecilians.

The torus is described by Wilczynski W. (1988) as the largest site for auditory processing in the anuran brain. The auditory torus has a central core surrounded by concentric shells. The most dorsal shell, the laminar nucleus, and the underlying, more caudal principal nucleus are both laminar structures with a subset of cells whose dendrites extend dorsoventrally into other layers. The ventral toral zone lies just above the tegmentum and is partially enclosed by the laminar and principal nuclei. The ventral toral zone consists of medium and large multipolar cells whose distributions vary within the ventral toral zone of different anurans. In some species, the large multipolar cells predominate in the ventral torus and are designated as the toral magnocellular nucleus.

The torus receives bilateral projections from the DMN, SO (ipsilateral predominance), and superficial reticular nucleus (or the nucleus of the lateral lemniscus). The ventral toral zone appears to be the major auditory integration site in the torus (Wilczynski, W., 1988). Some studies indicate there may be a loosely organized tonotopic organization with more high-frequency cells caudally and more low-frequency cells rostrally. Other studies have suggested a frequency map with concentric circles, resulting in lower-frequency cells surrounded by higher-frequency cells during vertical physiological excursions through the torus (discussed in Fuzessery, Z. M., 1988; Feng, A. S. and Schellart, N. A. M., 1999). Detection of a map is confounded by differences in tuning curves (broad vs. narrow) for torus cells and the convergence of other sensory systems in the torus that result in multimodal cells in all three subdivisions.

Physiological studies in the torus of anurans have revealed complex frequency responses, including cells that respond best to two or three simultaneous tones, cells with discontinuous tuning curves (e.g., intermediate frequencies are inhibitory), and cells that require very specific stimulus durations (Gooler, D. M. and Feng, A. S., 1992). Overall, the anuran torus has cells that exhibit complex acoustic feature detection, but there are still a few cells that retain primarylike responses. Feng A. S. and Schellart N. A. M. (1999) provide a more detailed discussion of the auditory response properties documented in the torus of anurans.

3.30.3.4 The Auditory Forebrain of Anurans

Cells in the auditory torus project to the central and posterior nuclei of the thalamus, though the projections are not distributed equally (McCormick, C. A., 1999). The central thalamic nucleus has reciprocal connections with the magnocellular and principal nuclei of the torus and also receives direct input from the SO. The posterior thalamic nucleus receives input primarily from the laminar nucleus of the torus. Hall J. C. and Feng A. S. (1987) suggested that the central and posterior thalamic nuclei conduct parallel processing for temporal and spectral aspects of sound, respectively. However, Neary T. J. (1988) suggested that the posterior nucleus integrates sensory information and is best thought

of as multimodal rather than acoustic based on extensive visual and somatosensory inputs. Although a third subdivision of the thalamus, the anterior nucleus, responds to acoustic stimuli, this area also receives substantial visual and somatosensory inputs (Neary, T. J., 1988).

Feng A. S. and Schellart N. A. M. (1999) suggest that signal discrimination in frogs such as conspecific, nonpredator, or predator may lie in the coincident activity of groups of cells in the thalamus, forming a population code whose activity reflects the convergence of various acoustic characteristics encoded at lower levels of the auditory pathway. This population code idea is an attractive one, since a similar organization has been suggested for other sensory systems in vertebrates.

The central thalamic nucleus projects to the hypothalamus and the preoptic area in the diencephalon, and to the striatum of the telencephalon. The anterior thalamic nucleus also sends light projections to the hypothalamus and the pallium of the telencephalon (primarily medial). Neither the preoptic area nor the hypothalamus are involved in auditory processing, but both are components of the circuitry that regulates seasonal, reproductive sound production. The role of the telencephalon may primarily be descending feedback pathways to coordinate behavioral responses to the relevant aspects of the auditory scene.

3.30.4 Functional Organization in Reptilia

The reptilia or sauropsida are a clade that includes turtles (Testudines), snakes and lizards (Lepidosauria), crocodiles and their relatives (Crocodilia), and birds (Aves), as well as a number of extinct groups. The birds and crocodiles (Archosaurs) are more closely related to each other than they are to lepidosaurs, while the position of turtles is controversial (Hedges, S. B. and Poling, L. L., 1999). Because birds arise from within the group traditionally considered to be reptiles, systematists now consider birds to be a subgroup within Reptilia. Most archosaurs are vocal, and birds have provided a major model for studies of complex sound processing and vocal communication.

3.30.4.1 The Auditory Periphery of Reptilia

Reptilia usually have an external ear and tympanum, with the only exception being Sphenodon, the surviving member of the order Rhynchocephalia, and the only living genus that shows an unmodified diapsid skull. Reptilia have one middle ear bone, the columella, which connects the tympanum and the oval window. The hearing organ of turtles, lizards, and archosaurs develops as an out-pocket from the saccule (Morsli, H. *et al.*, 1998). This ear has a new feature, the elongate basilar membrane (Wever, E. G., 1978). The evolution of the stereotypical basilar papilla of modern amniotes appears to have begun with the stem reptiles (Miller, M. R., 1980; Manley, G. A., 2000), and its key features are seen in turtles. The turtle basilar papilla is a flat strip of membrane populated by approximately 1000 tonotopically organized hair cells (see Chapter Phylogeny and Evolution of Ciliated Mechano-Receptor Cells). Salient features in papilla evolution include lengthening and curvature of the sensory epithelia, features thought to both enhance sensitivity and extend the audible frequency range (Manley, G. A. and Gleich, O., 2000).

The major tetrapod lineages are thought to have diverged from the stem reptiles quite early, and the ears of these groups are believed to have evolved in parallel. Tonotopic organization and the elongation of the papilla is seen in all groups. In addition, lizards display a unique population of free-standing hair cells that are not associated with a tectorial membrane. Free-standing hair cells are thought to be an adaptation that enables lizards to respond to higher frequencies (Manley, G. A. and Gleich, O., 2000). Tectorial hair cells in lizards resemble those found in birds and mammals. Usually lizard auditory nerve fibers encode low-center frequencies (100–800 Hz) and have sharp asymmetric tuning curves. Fibers from free-standing hair cells have high center frequencies (900–4000 Hz), high spontaneous rates, and broad symmetric tuning curves.

The basilar membrane of birds contains rows of hair cells that vary in height across the membrane. The number varies with species, with about 16 000 hair cells in the barn owl, 17 000 in the emu, and 6000 in the starling (Köppl, C., 2001). The avian basilar membrane does not contain the two types of hair cells found in mammals, but there are differences in innervation. Tall hair cells closest to the neural edge of the papilla provide the most afferent input to the auditory nerve dendrites, while short hair cells furthest from the neural edge receive purely efferent innervation. In general, the height of the hair cell stereocilia varies smoothly from one end of the papilla to the other, with long stereocilia at the apical low-frequency end of the papilla, and short stereocilia at the basal

high-frequency end. Birds hear higher frequencies than turtles, snakes, and lizards (Dooling, R. J., 2000; Klump, G., 2000). Most birds hear up to 5–6 kHz, while the barn owl has exceptional high-frequency hearing, with characteristic frequencies of 9–10 kHz in the auditory nerve (Konishi, M., 1973).

Additional auditory sensitivity to lower frequencies may be contributed by the saccule. In reptilia and mammals, the saccule had been assumed to be purely vestibular. Auditory sensitivity has been shown in reptiles (Lewis, E. R. and Narins, P. M., 1998), birds (Wit, H. *et al.*, 1984), and mammals (Young, E. D. *et al.*, 1977), however, and an accumulating body of evidence suggests that the saccule has retained some acoustic sensitivity (see Todd, N. P. and Merker, B., 2004 for review).

3.30.4.2 The Auditory Medulla of Reptilia

Tonotopic organization appears to be a key feature of the central auditory system of birds and crocodilians. Each point on the basilar membrane projects to an isofrequency plane across the extent of the first-order auditory nuclei. Thus the cochlear place representation is expanded into a second dimension in the brain, unlike the visual and somatosensory systems, which are point to point. These tonotopic sheets are preserved all the way to the forebrain, although it is not clear what features are processed in these isofrequency slabs. Divergent and convergent connections within isofrequency planes may be observed at all levels.

The reptilian central auditory system is organized in a common plan (Carr, C. E. and Code, R. A., 2000; Figure 1, Table 1). The auditory nerve enters the brain and divides into two, with the ascending branch terminating in the nucleus angularis and the descending branch in the nucleus magnocellularis. Except in some lizards, the nucleus magnocellularis projects to the nucleus laminaris, which in turn projects to the superior olive, to the lemniscal nuclei, and to the central nucleus of the auditory midbrain. The nucleus angularis projects to the superior olive, to the lemniscal nuclei, and to the central nucleus of the auditory midbrain. The parallel ascending projections of angularis and laminaris may or may not overlap with one another. Hindbrain auditory connections are generally bilateral, although contralateral projections predominate.

The evolutionary relationships among the elements of the central auditory systems of reptiles and mammals are beginning to be assessed using developmental comparisons. The early development of the avian hindbrain has been described in terms of rhombomere(r)-derived domains (Marin, F. and Puelles, L., 1995; Cramer, K. S. *et al.*, 2000). The nuclei of the lateral lemniscus originate between r1 and r3; nucleus angularis from r3 to r6; nucleus laminaris mostly from r5 with a small contribution from r6; nucleus magnocellularis from r5, r6, and r7; and the superior olivary nucleus from r5. The vestibular and sensory trigeminal columns both extend from r1 caudal throughout the hindbrain. A new study of the origins of the mouse cochlear nuclei has revealed distinct and not entirely overlapping origins from those observed in the chicken. The neurons of the cochlear nuclei arise largely from r2–r5, although a contribution arising from more caudal territories cannot be ruled out (Farago, A. F. *et al.*, 2006).

The first-order auditory nuclei encode parallel ascending auditory information streams (compare with other vertebrate nuclei in Table 1). In the owl, the nucleus magnocellularis is the origin of a neural pathway that encodes timing information, while a parallel pathway for encoding sound level originates with nucleus angularis (Takahashi, T. *et al.*, 1984). Auditory responses in the nucleus angularis include primarylike, onset, chopper, and complex-type-IV responses (Köppl, C. and Carr, C. E., 2003). Recordings in the chicken cochlear nuclei have found a similar but less clear segregation of function (Warchol, M. E. and Dallos, P., 1990). The similarities between the owl and the chicken suggest that the functional separation of time and level coding is a common feature of the avian auditory system. Although the anatomical divisions into angular and magnocellular nuclei characterize turtles, lizards, and archosaurs, there are no similar physiological data from turtles and lizards.

The auditory system uses phase-locked spikes to encode the timing of the stimulus. Phase-locking underlies accurate detection of temporal information, including detection of ITDs and gap detection (see Chapters Biophysical Specializations of Neurons that Encode Timing and Encoding of Interaural Timing for Binaural Hearing). Neural substrates for phase locking include the specialized endbulb terminal in the nucleus magnocellularis, termed an endbulb of Held. This large synapse has been documented in mammals, birds, and crocodilians, and conveys the phase-locked discharge of the auditory nerve fibers to its postsynaptic targets in the nucleus magnocellularis (see Chapter Central Synapses that Preserve Auditory Timing). Alpha-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA)-type glutamate receptors

contribute to the rapid response of the postsynaptic cell by virtue of their rapid desensitization kinetics (Parks, T. N., 2000). In birds, the nucleus magnocellularis projects to the nucleus laminaris, where sensitivity to ITDs emerges (see Chapter Encoding of Interaural Timing for Binaural Hearing). In the barn owl and chicken, nucleus laminaris neurons generate ITD selectivity by coincidence detection between binaural excitatory inputs and encode ITD in a place map according to the Jeffress model (Chapter Encoding of Interaural Timing for Binaural Hearing).

The lemniscal nuclei are located caudal and ventral to the auditory midbrain. There are two identified lemniscal nuclei in lizards and turtles (dorsal and ventral) and three in birds (dorsal, intermediate, and ventral). They receive input from the first-order auditory nuclei and from the nucleus laminaris, and they project to midbrain, thalamic, and forebrain targets. The dorsal lemniscal nucleus mediates detection of interaural level differences (ILDs) in the barn owl, which are important for the determination of elevation of sound sources (Konishi, M., 2003). The ILD pathway begins with the nucleus angularis, which responds to changing sound levels over about a 30 dB range (Köppl, C. and Carr, C. E., 2003). Each nucleus angularis projects to the contralateral dorsal nucleus of the lateral lemniscus, where sensitivity to ILDs emerges. Since dorsal lemniscal neurons do not encode elevation unambiguously, they are described as sensitive to ILD, but not selective because they are not immune to changes in sound level. The encoding of elevation improves in the auditory midbrain.

3.30.4.3 The Auditory Midbrain of Reptilia

The auditory midbrain in reptilia is termed the torus semicircularis or inferior colliculus. It receives ascending input and projects to the thalamus. It is surrounded rostrally and laterally by an intercollicular area that receives descending input from the forebrain archistriatum (Puelles, L. *et al.*, 1994). The auditory midbrain mediates auditory processing, while the intercollicular area appears to mediate vocalization and other auditory-motor behaviors.

In birds, the auditory midbrain is divided into an external nucleus and a central nucleus. The nucleus angularis, lemniscal nuclei, and nucleus laminaris project to regions of the central nucleus (Conlee, J. W. and Parks, T. N., 1986; Takahashi, T. T. and Konishi, M., 1988). Studies of the owl auditory midbrain have shown that most neurons are binaural, excited by inputs from the contralateral ear and inhibited by the ipsilateral ear, although bilateral excitation and contralateral excitation are also present. The tonotopic organization is consistent with the tonotopy observed in lizards and crocodiles, with low best frequencies dorsal.

Physiological recordings from the midbrain in barn owls and songbirds show the emergence of biologically relevant responses (Konishi, M., 2003; Woolley, S. M. *et al.*, 2005). Behavioral studies have identified the relevant stimulus features for barn owl sound localization (Takahashi, T. T. *et al.*, 2003). These nocturnal predators have excellent sound localization ability, and their midbrain responses are dominated by binaural computations underlying localization. Most barn owl inferior colliculus neurons are binaural, and many are sensitive to changes in ILD and ITD. Physiological properties are subdivision specific and reflect the inputs to each subdivision. The central nucleus projects both to the auditory thalamus and external nucleus. Space-specific responses emerge in the external nucleus (Konishi, M., 2003; Takahashi, T. T. *et al.*, 2003). The external nucleus projects topographically to the optic tectum, which contains aligned maps of visual and auditory space. Activity in the tectum directs the rapid head movements made by the owl in response to auditory and visual stimuli (Knudsen, E. I. *et al.*, 2000).

3.30.4.4 The Auditory Forebrain of Reptilia

In reptilia, the central nucleus of the auditory midbrain projects bilaterally to a dorsal thalamus region made up of a central nucleus surrounded by a shell (Grothe, B. *et al.*, 2004). The core and shell receive ascending input from the central nucleus and from the lemniscal nuclei, respectively. In both birds and crocodilians, the core and shell thalamic regions project to separate, nonoverlapping regions of forebrain, suggesting a basic division of auditory input to the forebrain into two separate streams (Grothe, B. *et al.*, 2004). Although the connections and dorsal thalamic locations are consistent throughout amniote phylogeny, suggesting these structures are homologous, the anatomical terminology differs. The dorsal thalamus is called nucleus reuniens in turtles, nucleus medialis in lizards and crocodilians, and nucleus ovoidalis in birds. The avian nucleus ovoidalis is tonotopically organized, with high best frequencies located dorsally, and low best frequencies ventrally. There is not a great deal known about the physiological properties of the auditory dorsal thalamus. In

the barn owl, all divisions of the central nucleus project to the nucleus ovoidalis, and the physiological responses in ovoidalis reflect this diverse array of inputs. Most neurons respond to ITD and/or ILD, at stimulus frequencies similar to those found in the midbrain. In contrast to the mapping found in the owl midbrain, however, nucleus ovoidalis contains no systematic representation of sound localization cues. Nevertheless, space-specific responses are found in the forebrain, and sound localization and gaze control are mediated in parallel in the midbrain and forebrain of the barn owl (Konishi, M., 2003).

In birds, the nucleus ovoidalis projects to field L (Karten, H. J., 1968; Wild, J. M. *et al.*, 1993). Field L is the primary auditory area of the avian telencephalon, and is divided into three parallel layers; L1, L2, and L3, with L2 further divided into L2a and L2b. Auditory units in L2 generally have narrow tuning curves with inhibitory sidebands, which might be expected from their direct input from the dorsal thalamus, while the cells of L1 and L3 exhibit more complex responses (Karten, H. J., 1968; Scheich, H. *et al.*, 1979). The general avian pattern is that Field L projects to the adjacent nidopallium and to other nuclei of the caudal nidopallium. These nidopallial nuclei project to the auditory areas of the arcopallium (ventromedial nucleus of the intermediate arcopallium (AIVM), robust nucleus of the arcopallium (RA)), which project back down to the auditory thalamus and midbrain (Carr, C. E. and Code, R. A., 2000). Karten H. J. (1968) has hypothesized that the organization of the ovoidalis to field L circuit in birds resembles the pathway in mammals from the ventral medial geniculate nucleus to primary auditory cortex (see Reiner, A. *et al.*, 2005 for review).

The auditory forebrain exhibits large changes associated with the increased use of sound for communication in archosaurs and mammals. In the archosaurs, the clearest examples are the specialized communication systems that have evolved in parallel in songbirds, parrots, and humming birds. Birds that learn their vocal motor behavior have a strong dependence on hearing. Their telencephalic song system is composed of an anterior and posterior pathway. The posterior pathway is composed of a circuit from the higher vocal center (HVC) to the RA and then down to the motor nuclei that control the syrinx and respiration (Nottebohm, F., 1980; Brainard, M. S. and Doupe, A. J., 2000). The posterior pathway is required throughout life for song production. The anterior forebrain pathway is a basal ganglia–forebrain circuit critical for song learning and for adult modification of vocal output. The anterior pathway projects to the posterior pathway, and is thus well positioned to provide a guiding influence on the developing vocal motor program.

The anterior pathway is homologous to basal ganglia circuits in mammals (Bottjer, S. W. and Johnson, F., 1997). A modern revision of the avian anatomical nomenclature has provided a common language for studying the function of the cortical–basal ganglia–cortical loop, enabling neuroscientists to take advantage of the specialization of basal ganglia areas in various birds (Doupe, A. J. *et al.*, 2005; Jarvis, E. D. *et al.*, 2005). In both birds and mammals, the basal ganglia contain similar cell types, which project to the midbrain substantia nigra and globus pallidus, and receive a major glutaminergic input from the overlying pallium, dopaminergic input from the midbrain, and a lesser glutamatergic input from the thalamus. The two types of striatal projection neuron, a substantia nigra and a globus pallidus are present in all jawed vertebrates, supporting the idea that the basal ganglia performs a fundamental role in telencephalic function (Doupe, A. J. *et al.*, 2005). Studies of the role of the anterior pathway in auditory learning are illuminating the interaction between sensory, motor, and reward signals in the basal ganglia, and the function of these signals in task learning and execution.

3.30.5 Functional Organization in Mammals

Mammals are a monophyletic group composed of the placental mammals (or eutheria) and two sister taxa, the monotremes and marsupials (Janke, A. *et al.*, 1997). One of the defining mammalian characters is the presence of three middle ear bones. Mammals also differ from other vertebrates in often having moveable external ears and sensitivity to high-frequency sound. The mammalian central auditory system is further characterized by the addition of type II auditory nerve fibers and by additional nuclei including the dorsal cochlear nucleus (DCN), the nuclei of the trapezoid body, and multiple olivary nuclei. The mammalian auditory system has been the subject of numerous books and articles, and will only be briefly reviewed here.

3.30.5.1 The Auditory Receptors of Mammals

Mammals usually have external ears that collect sound and act as directional filters. Three middle ear bones work together as a lever system to amplify the force of sound vibrations (see Chapter Mechano-Acoustical Transformations). In mammals, auditory hair cells in the cochlea (Figure 3(b)) are organized on the basilar membrane into rows of inner and outer hair cells. Inner hair cells innervate type I primary afferents and are innervated by a very few efferents. Outer hair cells sparsely innervate by type II primary afferents and receive more efferent terminals.

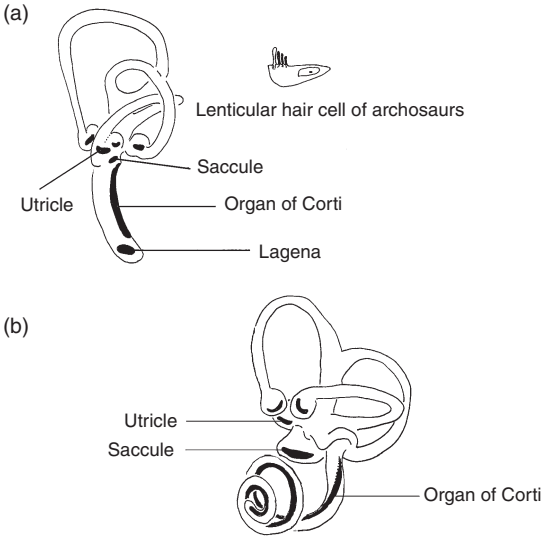

Figure 3 Comparison of archosaurian and mammalian inner ears. The branching of nerve VIII has not been included. The semicircular canal cristae of the vestibular system are shown but not labeled (compare to Figure 2). (a) Generalized archosaur ear (crocodilian/avian). Note the relationship between the lagena and the elongate basilar papilla (also called the basilar membrane and organ of Corti). The archosaurs have a unique lenticular hair cell, which varies in shape and frequency response with location along the basilar membrane (see figures 3.1 and 3.5 in Gleich, O., and Manley, G. A., 2000). (b) Generalized mammalian ear (guinea-pig). Note the loss of the lagena and the impressive increase in the length of the organ of Corti (cochlea), associated with a greater range of frequency sensitivity than found in archosaurs. Mammalian hair cells lack a kinocilium and are oriented identically all along the cochlea, with systematic changes in surface morphology correlated to their frequency response. Note that micromechanical factors also influence frequency sensitivity along the cochlea. Adapted from Lewis, E. R., Leverenz, E. L., and Bialek, W. S. 1985. The Vertebrate Inner Ear. CRC Press.

Mammals hear relatively high frequencies compared to other vertebrates. Most mammals hear up to 20 kHz, while microchiropteran bats and some toothed whales have evolved high-frequency hearing for use in sonar, with characteristic frequencies of 50–120 kHz. Some mammals (e.g., elephants and baleen whales) are sensitive to infrasound, which they use for communication (Payne, K. *et al.*, 1986; Edds-Walton, P. L., 1997). Auditory sensitivity has been documented in saccular afferents of guinea-pigs, cats, and squirrel monkeys (see Todd, N. P. and Merker, B., 2004 for review). Saccular responses are like those associated with type I hair cells, with a best stimulus frequency between about 200 and 1000 Hz, and a rate threshold of about 90 dB sound pressure level (SPL).

3.30.5.2 The Auditory Medulla of Mammals

The auditory nerve enters the brain and divides into two, with the ascending branch projecting to the anterior region of the ventral cochlear nucleus (VCN) and the descending branch to the posterior region of the VCN and to the new DCN. The cochlear nucleus complex develops modularly from progenitor populations arrayed as rostrocaudal microdomains both within and outside the lower rhombic lip region of rhombomeres 3–5 (Farago, A. F. *et al.*, 2006). VCN subdivisions arise from more rostral lower rhombic lip than the DCN, which arises from the region of rhombomere 5, both caudal and noncontiguous to the cerebellar primordium. Thus, although the DCN has a laminar, cerebellum-like organization that includes a granule cell system (Oertel, D. and Young, E. D., 2004), its embryonic origins suggest that it is evolutionarily separate from the cerebellar primordium in rhombomere 1. The VCN contains both large cells and a granule cell cap. These two populations are also embryonically separable, since VCN neurons arise from lower rhombic lip and coaxial nonlip progenitors while the granule cells derive principally from the lower rhombic lip (Farago, A. F. *et al.*, 2006).

The auditory nerve contains both type I and type II afferents. Type I are the most numerous, receive sharply tuned inputs from inner hair cells, and send thick myelinated axons into the brain. Type II afferents are assumed to be unique to mammals, are innervated by outer hair cells, and have thin, unmyelinated axons. They project to granule cell regions of VCN and DCN, and also are involved in the efferent feedback circuit to the cochlea (Ryugo, D. K. and May, S. K.,

1993). Tonotopy is preserved in the projections of the auditory nerve. In mammals, the ventral part of each cochlear nucleus receives low-frequency (apical) input and dorsal areas receive high-frequency input. The auditory nerve forms different types of terminals onto different cell types in the cochlear nucleus (Ryugo, D. K. and May, S. K., 1993). Endbulb of Held terminals are formed on bushy cells (see below), while more varicose or boutonlike terminals are formed on other cell types in the cochlear nuclei. The auditory nerve appears to use glutamate as a transmitter, often with the postsynaptic cell expressing fast AMPA-type glutamate receptors that can mediate precise temporal coding (Parks, T. N., 2000; see Chapter Central Synapses that Preserve Auditory Timing).

There are nine distinguishable projection neurons in the cochlear nucleus – seven in the VCN and two in the DCN (Rouiller, E. M. and Ryugo, D. K., 1984; Rhode, W. S., 1991; Young, E. D., 1998; Cant, N. B. and Benson, C. G., 2003). In the VCN, bushy cells receive endbulb inputs from the auditory nerve and exhibit accurate temporal coding (see Chapter Biophysical Specializations of Neurons that Encode Timing). Spherical bushy cells dominate the anterior VCN, respond to lower best frequencies, and project to the medial superior olive (MSO), which is sensitive to ITDs. Globular bushy cells respond to higher frequencies and project to the lateral superior olive (LSO) and the medial nucleus of the trapezoid body (MNTB). These projections may mediate detection of ILDs (see Chapter Encoding of Interaural Level Differences for Sound Localization). Octopus cells in the posterior VCN are multipolar, with thick dendrites that extend across the nerve root (Oertel, D. *et al.*, 2000). This morphology enables them to integrate auditory nerve inputs across a range of frequencies. Octopus cells encode the time structure of stimuli with great precision and exhibit onset responses to tonal stimuli (Oertel, D. *et al.*, 2000). Onsets play an important role in theories of speech perception, and segregation and grouping of sound sources (Bregman, A. S., 1990).

The DCN appears for the first time in mammals, and is assumed to have evolved with the development of high-frequency hearing and motile external ears. It is composed of a cerebellar-like circuit in the superficial layers, with projection cells below that receive auditory nerve inputs (Oertel, D. and Young, E. D., 2004). The granule cells in the superficial layers receive ascending somatosensory input that may convey information about head and ear position. The deep portion of the DCN contains fusiform and stellate cell types. Fusiform cells exhibit complex (type IV) frequency tuning curves, with small areas of excitation at best frequency and at sides. This response is well suited to detecting the notches in sound level created by the external pinna, which provide cues for locating sound in elevation (Brown, C. and May, B. J., 2005).

The olivary nuclei regulate the binaural convergence of acoustic information and mediate spatial hearing. Neural computations for sound localization begin at this first site of binaural convergence. The LSO encodes ILD (see Chapter Encoding of Interaural Level Differences for Sound Localization), while the MSO encodes time differences (see Chapter Encoding of Interaural Timing for Binaural Hearing). Information conveyed by temporal and rate codes appears to be transformed in the olivary nuclei into codes for location. The LSO principal cells receive excitatory inputs from ipsilateral globular bushy cells, and inhibitory glycinergic inputs onto their cell bodies and proximal dendrites, relayed from the contralateral ear via the MNTB. The MNTB input acts to reverse the sign of bushy cell input from excitatory to inhibitory to make an EI response and create sensitivity to ILDs (see Chapter Encoding of Interaural Level Differences for Sound Localization). In general, as the strength of the contralateral input increases with increasing loudness in the contralateral ear, the maximum rate decreases. Thus, LSO firing rate signals a range of ILDs (for review, see Kuwada, S. *et al.*, 1997).

Sensitivity to ITDs originates in the MSO (see Chapter Encoding of Interaural Timing for Binaural Hearing). Neurons of the MSO act as coincidence detectors, as do the neurons of the reptilian nucleus laminaris. Nevertheless, there may be differences in how birds and mammals encode ITDs. Recent evidence from guinea-pigs and gerbils indicates that in mammals, ITDs are not represented by maximal discharges of a small subpopulation of neurons within one frequency contour, but rather by the relative activity of the frequency contours of both MSOs. This activity is regulated by inhibition, not delay-lines (see reviews in Grothe, B., 2003; McAlpine, D. and Grothe, B., 2003). It is possible that neuronal representation of auditory space differs in reptiles and mammals indicating again a parallel, independent evolution of spatial hearing (Grothe, B. *et al.*, 2004).

There are three mammalian lemniscal nuclei: ventral, intermediate, and dorsal. They receive projections from the cochlear nuclei and olivary complex (Cant, N. B. and Benson, C. G., 2003). The ventral lemniscal

nucleus contains a columnar region characterized by broad-frequency tuning and temporally precise inputs that encode stimulus onset time. The dorsal lemniscal nucleus is largely binaural, and receives ITD information from the superior olivary complex. The dorsal lemniscal nucleus provides a strong GABAergic inhibitory input to the inferior colliculus, and may serve to transform the coding of ITDs there (Winer, J. A. *et al.*, 1995; Kuwada, S. *et al.*, 2006).

3.30.5.3 The Auditory Midbrain of Mammals

The inferior colliculus is the midbrain target of ascending auditory information. It has three major divisions, the central nucleus, the lateral nucleus, and dorsal cortex (see Winer, J. A. and Schreiner, C. E., 2005). In the central nucleus, the inputs from brainstem auditory nuclei are either distributed across or superimposed upon maps to form what are believed to be locally segregated functional zones for processing different aspects of the auditory stimulus (Oliver, D. L. and Morest, D. K., 1984; Ehret, G., 1997; Covey, E. and Carr, C. E., 2005; Winer, J. A. and Schreiner, C., 2005). The central nucleus receives both direct monaural input and indirect binaural input (Winer, J. A. and Schreiner, C., 2005). Physiological studies show both binaural and monaural responses (Ehret, G., 1997), and the emergence of coding for biologically important parameters. Input sources include the cochlear nucleus, olivary complex (Glendenning, K. K. *et al.*, 1992), lemniscal nuclei, and descending inputs from auditory cortical areas (Winer, J. A. *et al.*, 1998). There are also commissural and intrinsic projections. The inferior colliculus projects back to almost all auditory brainstem nuclei, and projects bilaterally to the auditory thalamus.

The central nucleus is exclusively auditory and is essential for normal hearing, the lateral nucleus is multisensory, and the dorsal cortex receives most of its projections from the cerebral cortex. Physiological properties that arise in the auditory midbrain distinguish it from medullary auditory nuclei, and Casseday J. H. and Covey E. (1996) have proposed that tuning processes in the inferior colliculus are related to the biological importance of sounds. They propose that the changes in timing properties at the inferior colliculus, from rapid input to output timing related to the timing of specific behaviors.

3.30.5.4 The Auditory Forebrain of Mammals

In mammals, the ascending auditory projections share many features with other vertebrates, although the origins and homologies of mammalian cortex are not yet well understood (Aboitiz, F. *et al.*, 2003). The isocortex is a distinctive feature of mammalian brains, and has no clear counterpart in the cerebral hemispheres of other amniotes. Current studies suggest that the isocortex may have originated from the dorsal pallium (Northcutt, R. G. and Kaas, J. H., 1995). As in birds and frogs, the auditory regions of the mammalian forebrain exhibit large changes in size and number of auditory areas, possibly associated with the increased use of sound for communication.

Mammalian auditory cortex receives ascending input from the medial geniculate complex. Primary auditory cortex (A1) generally contains three primary-like areas that are tonotopically organized and highly responsive to pure tones (see Chapter The Functional Neuroanatomy of the Auditory Cortex). Auditory information is then distributed from these core areas to surrounding belt regions that are less precisely cochleotopic and generally more responsive to complex stimuli. Belt and parabelt regions may be concerned with integrative and associative functions involved in pattern perception and object recognition. At least one tonotopic representation has been found in all species studied. Primitive mammals like tenrecs have few auditory areas (Krubitzer, L. *et al.*, 1997), there are at least seven tonotopic maps in the cat and mustached bat (Winer, J. A., 1992), and eight in the macaque monkey (Petkov, C. I. *et al.*, 2006).

Functional analyses demonstrate independent processing streams for sound localization and identification, analogous to the what and where streams in visual cortex (Rauschecker, J. P. and Tian, B., 2000). The nature of both these streams is still elusive. Spatial representation (where) in the mammalian auditory cortex has proven to be a difficult issue. Unlike the superior colliculus, there is no topographic organization of binaural cues or spatial sensitivity (see Chapter Sound Localization and the Auditory Cortex). Detection of salient sounds (what) is also only incompletely understood. Recordings from marmoset auditory cortex reveal very similar preferences for species-specific vocalizations to those found in songbirds.

Mechanisms underlying the emergence of responses to complex sounds also have been addressed in the most vocal mammals, bats, which use sound for both echolocation and communication. Bats determine

target distance from the time delay between their sonar vocalizations and the returning echoes and use the three-dimensional information about target location to guide the features of their sonar vocalizations. In the mustached bat (*Pteronotus parnellii*), numerous auditory cortical areas are related to identification of echolocated prey. A1 systematically represents frequency with an enlarged representation of the Doppler shift compensation region, mapping not just frequency, but amplitude. There are several maps of echo delay, for delays that represent near, mid-range, and far targets. There are also maps of the contralateral azimuth and a second Doppler shift region. Suga N. (1988) has used these data to construct a parallel-hierarchical scheme for signal processing. Two major principles have emerged from studies of bat auditory processing. First, since different components of echolocation calls differ in frequency, they are processed in parallel channels in the auditory system by virtue of their tonotopy. In the cortex, however, combination sensitive neurons may be created by comparing across frequency channels (Suga, N., 1988). Second, this work has shown that the auditory system has the potential for reorganization as a function of experience. In particular, corticofugal projections can affect the properties of subcortical neurons in response to sound (Suga, N. and Ma, X., 2003).

3.30.6 Summary

There are exceptions that limit our ability to make generalizations about auditory processing that apply to all members of any vertebrate group. While all vertebrates hear, there is great variation in their auditory periphery and in the frequencies detected. Nevertheless, phase-locking, frequency tuning, temporal sensitivity, and binaural processing are present in all vertebrates.

Fishes lack an outer ear but have auditory end organs that function similarly to those of terrestrial vertebrates. The auditory epithelia are stimulated by particle motion, with best frequencies below 500 Hz being most common. Physiologically polarized hair cells are oriented in various directions within and among the auditory end organs of fishes, and form an anatomical basis for sound source localization. Pressure sensitivity is a specialization found primarily in freshwater fishes, usually accompanied by an extended sensitivity to higher frequencies.

Evolutionarily, the amphibians developed an external tympanum and a middle ear, plus a unique auditory inner ear end organ, the amphibian papilla, not found among other vertebrates. The tympanum/middle ear transduces air- or water-borne pressure waves into particle motion in the fluids surrounding the auditory end organs. Some also detect substrate vibrations via bone conduction. Sound source localization and discrimination of species-specific calls critical to reproduction appear to be the major driving forces in the organization of both the periphery and the central nervous system in anurans. Primary afferent responses are similar to those of fishes, but feature detection is well-developed at the midbrain level in anurans and the forebrain may primarily coordinate appropriate responses to input from auditory and other sensory systems.

Among the Reptilia, evolutionarily new specializations of the auditory periphery emerge, with an elongate basilar membrane, systematic variations in hair cell morphology and tonotopic organization. There is great variability in the auditory periphery of the lizards. Birds are the most intensively studied Reptilia, and provide a model for studies of complex sound processing and vocal communication. Parallel pathways for encoding interaural time and level differences mediate sound source localization.

Mammals have a further elongated and coiled cochlea in the inner ear with specialized inner and outer hair cells and great diversity in hearing capabilities, from infrasound to ultrasound. Localization was improved by the development of moveable external ears. The forebrain auditory processing areas are characterized by complex responses to auditory stimuli, including those related to sound source localization and communication.

Despite similarities in the organization of the central auditory systems of vertebrates, it is not clear whether the components are homologous, or whether the evolution of the central auditory system merely follows the organizational pattern common to the octaval system. The auditory processing observed in modern vertebrates shows many examples of parallel solutions to similar problems.

Glossary

auditory neuropil Projection area in the central nervous system of primary auditory afferents.
chordotonal organ A highly sensitive mechanoreceptive organ that comprises several scolopidial sensilla. Chordotonal organs insert on different parts in the body and have a proprioceptive function.
crista acoustica Hearing organ in the ear of Ensiferans, in which the auditory afferents are arranged tonotopically.
phonotaxis Orientation behavior toward or away from a sound source.
precedence effect Behavioral preference of animals for the earlier of two identical sound signals.
scolopidium An internal mechanoreceptive sensillum consisting of 1–3 bipolar sensory neurons with ciliated dendrites, a scolopale cell that forms a scolopale around the cilia and an attachment cell that links the sensillum to the cuticle.
template matching A mechanism proposed for auditory pattern recognition based on an internal template that is compared with any perceived acoustic signals.
tonotopy Mapping between sound frequency and the spatial distribution of cell bodies or axonal arborizations pattern of auditory afferents.
tympanic membrane Eardrum in the hearing organ of insects.

3.31.1 General Introduction

In comparison to olfaction or vision, hearing in invertebrates probably appeared only recently during evolution, as an adaptation to permit detection of sounds made by predators, especially by bats, or by acoustically active hosts, and to mediate intraspecific communication. Although many groups of invertebrates possess sensory organs capable of responding to sound (particularly in water), insects are the only group in which hearing is used widely. Indeed, the use of airborne acoustic signals in behavior by invertebrates is known, outside the insects, only for some crustaceans (Budelmann, B. U., 1992). Moreover, only scant information is available on the neurobiology of hearing in noninsect groups. Therefore, this chapter focuses exclusively on hearing in insects.

Two functionally different types of sound sensors evolved in insects, which exploit different physical principles and work in completely different frequency ranges. Tympanic membranes attached to some cuticular framework respond to acoustically mediated changes in the air pressure. Fragile elongated hair- or feather-like structures act as velocity receptors and respond to the coherent movements of air that occur close to a sound source. Velocity receptors are sensitive to sounds with frequencies well below 1 kHz, whereas sensitivity of pressure receivers is best for frequencies in the range of about 3–50 kHz and is poor for low frequencies due to constraints of body size. Auditory systems allow the insects to deal with several fundamental tasks:

1. The detection of predator signals to prepare for an evasive response.
2. The recognition and localization of species-specific acoustic communication signals, for example, for territorial spacing, mate attraction and/or the transfer of information on food resources.
3. The localization, by parasitoid insects, of acoustically conspicuous hosts.

But to do so auditory systems have to cope with self-generated sounds and with signal degradation due to the impact of motor activity on the auditory organs, and due to degradation of sound as it travels through the environment.

The acoustically induced oscillations of velocity or pressure receivers are picked up by auditory afferent neurons. In all insects the afferents of pressure receivers are components of scolopidia, which are

highly sensitive mechanosensory sensilla. The number of sensilla per ear may vary from a single one in some moths to more than a thousand in cicadas or mosquitoes. It is still a matter of debate to what degree absolute sensitivity and frequency tuning are determined by the biomechanical frequency analysis of the ears and/or by inherent active properties of the auditory sensilla. Spike activity of afferents is precisely timed to the onset of sound pulses and forwarded from the auditory afferents to first order interneurons in the thoracic ganglia.

The central auditory pathways are located in the thoracic ganglia and the brain. The principal tasks for processing may be summarized as follows:

1. Behaviorally relevant information, including the frequency, direction, and temporal pattern of acoustic signals, must be extracted from the spike trains of afferents.
2. This information must be distributed to decision-making centers, generally believed to reside in the brain, where features such as species identity, gender, and perhaps genetic quality of the signaler can be assessed.
3. Finally, information must be forwarded to the motor centers that generate behavioral responses to the acoustic signals.

Structural and functional specializations that support the various tasks of auditory processing appear to occur very early in the auditory pathway and allow parallel processing of specific auditory features within the central nervous system (CNS). Since thoracic auditory neuropils and even identified interneurons appear to be homologous in different groups of related insects, species-specific adaptations can be revealed.

We would like to note in passing that the terminology for auditory interneurons is not uniform. The same names are given to what may be nonhomologous neurons in different groups of insects; for example, a neuron named AN1 in crickets, a prothoracic neuron, is certainly nonhomologous with a metathoracic neuron of the same name in acridids. However, AN1s of crickets and tettigoniids are structurally and functionally similar, and thus may be homologs.

3.31.1.1 Distribution and Design of Ears

Hearing organs for the detection of sound pressure are generally composed of three components (Yager, D. D., 1999): a thin tympanic membrane that vibrates in response to acoustic stimulation; a cuticular frame that anchors the membrane; and an air-filled tracheal chamber that is apposed against the inner surface of the tympanal membrane to match the acoustic impedance of the surrounding air. From one (in some moths) to more than a thousand (in some cicadas) mechanosensitive scolopidial sensilla form the auditory organ and transduce the mechanical oscillations of the tympanum into series of action potentials in auditory receptor neurons. With the exception of some sensory hairs (sensilla trichodia) that can respond to particle velocity, scolopidial sensilla are the auditory sensors for all insect ears, reflecting the evolution of ears from chordotonal organs, which are also comprised of scolopidia (Boyan, G. S., 1993). The basic building blocks for acoustic pressure receivers (cuticle, membrane, and scolopidia) are present in almost all insects. This may explain partly the frequency with which pressure receivers have evolved independently (at least 12 times in eight orders of insects (Yager, D. D. and Spangler, H. G., 1995)), in at least ten different locations on the body (Yack, J. E. and Fullard, J. H., 1993). However, outside the group of insects, specialized hearing organs have not been described among invertebrates.

Long-distance acoustic signaling and hearing is used by the ancient bladder grasshopper *Bullacris membracioides* (van Staaden, M. J. and Römer, H., 1997; 1998; van Staaden, M. J. *et al.*, 2003). Auditory organs in males and females may represent an early evolutionary stage. They lack a tympanum but consist of chordotonal organs directly attached to the pleural cuticle of the abdominal segments A1–A6, the first containing about 2000 bipolar sensory neurons. In Lepidoptera, where pressure receivers have evolved several times, tympanal ears occur on the mouth (Roeder, K. D., 1972; Göpfert, M. C. and Wasserthal, L. T., 1999a; 1999b), the first abdominal segment (von Kennel, J. and Eggers, F., 1933; Roeder, K. D. and Treat, A. E., 1957), the thorax (Eggers, F., 1911; 1919; Richards, A. G., 1933) and the wings (Vogel, R. 1912; Yack, J. E. and Fullard, J. H. 1999; Yack, J. E. *et al.*, 2000). Ears situated on the wings also occur in lacewings (Miller, L. A. 1970; 1971).

In beetles, pressure receivers evolved in at least two groups independently. In scarab beetles (*Dynastinae*), ears are located in the cervical membrane behind the head with 3–8 scolopidia directly attached to the tympanic membrane (Forrest, T. G. *et al.*, 1997). In tiger beetles (*Cicindelidae*), hearing organs are positioned laterally on the first abdominal tergum (Spangler, H. G., 1988; Yager, D. D. and

Spangler, H. G., 1995). In the praying mantis (*Mantis religiosa*), pressure receivers are located in a groove stretching caudally along the midline of the metathoracic segment. The left and right tympana are formed by stiff nonmembranous cuticular ovals in the walls of the groove with large tracheal sacs adhering to the tympana from the inside. The tympanal organ contains about 32 scolopidial sensilla, which are attached to the anterior end of a tympanum by a ligament (Yager, D. D. and Hoy, R. R., 1986; 1987).

In the Hemiptera, tympanal hearing evolved at least twice, in cicadas (*Homoptera/Cicadidae*) and in water bugs (*Heteroptera/Corixidae*), both of which use sound for intraspecific signaling. In *Corixidae*, sounds are picked up by mesothoracic tympanal hearing organs containing two auditory afferents. The tympanic membranes are covered by an air-filled space that is enclosed by the basal parts of the wings and maintained when the animals dive (Wotzel, F., 1933; Schaller, F., 1951; Arntz, B., 1975; Prager, J., 1976). In *Cicadidae*, the auditory capsule containing the structures of the ear is located ventro-laterally between the first and second abdominal segments (Vogel, R., 1923; Michel, K., 1975; Young, D. and Hill, K. G. 1977). Each auditory organ contains about 1300–2200 auditory afferents (Michel, K. 1975; Doolan, J. M. and Young, D. 1981; Huber, F. *et al.*, 1990).

Pressure receivers have no inherent directional sensitivity but some directionality may be present due to sound diffraction at the animal's body, which is especially effective for short-wavelength ultrasound signals.

Pressure difference receivers are more complex and allow for access of the sound waves to both sides of the tympanic membrane. The oscillations of the tympanum depend on the amplitude and phase of the forces acting on the inside and outside respectively. Since these vary with the direction of sound incidence pressure difference receivers are therefore inherently directionally sensitive. Pressure difference receivers occur in the first abdominal segments of grasshoppers and in the tibiae of the front legs in crickets and katydids (Yager, D. D., 1999). In acridid grasshoppers, tympana are present in the pleura of the first abdominal segment (Schwabe, J., 1906). Both ears are acoustically coupled due to large air sacs within the abdomen that allow sound in the range of 3–5 kHz to pass through the body and act on the inside of the contralateral tympanum (Michelsen, A. and Rohrseitz, K., 1995; Schul, J. *et al.*, 1999). In bushcrickets and crickets, an air-filled acoustic trachea with a spiracular opening at the first thoracic segment acts like a hearing tube which guides sound into the tibia of the front leg where it can act upon the inner surface of the tympanum. In addition, in crickets branches of the left and right trachea meet at the midline and are functionally coupled by a median septum, permitting acoustical interaction between the two ears. Depending on the group and species about 20–70 auditory afferents are arranged along the length of the leg trachea, forming the hearing organ. The afferents are divided into anatomically distinct groups: a proximal group with about 10–20 sensilla (referred to as the *intermediate organ* in bushcrickets); a main group with up to 40 sensilla (the *crista acoustica*) and, in crickets, a distal group with about 10–20 sensilla (Ball, E. E. *et al.*, 1989).

In two groups of parasitic flies (*Tachinidae and Sarcophagidae*), evolution has driven the development of a different type of a highly directional hearing organ that is used by the females for locating and approaching singing crickets, bushcrickets or cicadas (Lakes-Harlan, R and Heller, K.-G. 1992; Robert, D. *et al.*, 1992). These ears are located at the midline of the ventral prosternum and comprise two tympanal membranes backed by an air-filled chamber in the sternum. Although the design varies in different species (Robert, D. *et al.*, 1994; Robert, D. *et al.*, 1999; Lakes-Harlan, R. *et al.*, 1999) as a functional principle both membranes are mechanically coupled. The hearing organs (*bulba acoustica*) are located within the air sac behind the tympanal membranes and comprise about 90–100 (*Ormia ochracea*) or 200 (*Therobia leonideii*) auditory afferents, which are attached to each tympanum (Stumpner, A. and Lakes-Harlan, R., 1996; Oshinsky, M. L. and Hoy, R. R., 2002).

3.31.2 Peripheral Processing

3.31.2.1 Central Projections of Auditory Receptors

The anatomical substrate for the first level of central processing, that is, that of first-order interneurons, is established by the projections to the CNS of auditory receptors. We will first discuss some general issues regarding central projections before considering in detail the functional organization of the afferent projections in the few insects in which this has been analyzed.

3.31.2.1.1 Common features of receptor projections

In all systems studied to date, receptor neurons of one side (i.e., left or right) project to the same side of

the CNS (moths: Surlykke, A. and Miller, L. A., 1982; mantises: Yager, D. D. and Hoy, R. R., 1987; flies: Lakes-Harlan, R. *et al.*, 1999; cicadas: Wohlers, D. W. *et al.*, 1979; Doolan, J. M. and Young, D., 1981; see below for references for crickets, locusts, and tettigoniids). Only in mantises and cicadas have a few fibers been described as crossing the midline. Presumably, keeping input from the two ears separate facilitates binaural comparison at the interneuron level, which forms the basis for sound localization (see below).

A second common finding is that axonal projections are generally plurisegmental (references as above); single afferents form terminal arbors in several adjacent ganglia (or neuromeres of fused ganglia) within the CNS. For example, afferents of the locust may have axonal branches in all three thoracic ganglia and also in one or more abdominal neuromeres that form part of the metathoracic ganglion complex (Jacobs, K. *et al.*, 1999). The A1 afferent of noctuid moths has an even more extensive reach. The axon proceeds to the head ganglia, probably to the brain (although the final arborizations in the brain have not yet been demonstrated (Surlykke, A and Miller, L. A. 1982, Boyan, G. S. *et al.*, 1990). Plurisegmental projections of auditory afferents also occur in cicadas (Wohlers, D. W. *et al.*, 1979; Doolan, J. M. and Young, D., 1981), mantises (Yager, D. D. and Hoy, R. R., 1987 and flies (Lakes-Harlan, R. and Heller, K-G., 1992). A different scheme is found in the ensiferans (crickets and tettigoniids), where the axonal arborizations of auditory afferents are restricted to the prothoracic ganglion.

Despite the enormous variation in the locations and structures of insect ears, the central neuropils in which the axonal branches of auditory afferents terminate are similar across many insects. The internal organization of insect ganglia is highly structured, and specific axon tracts, commissures, and neuropil regions can be recognized across taxa. In each segmental ganglion, a region, variously known as the anterior ring tract, the medial ventral association center (mVAC), or the anterior intermediate sensory neuropil (iASN), is the target of auditory afferents of insects as diverse as moths, flies, crickets, grasshoppers, katydids, and wetas (Wohlers, D. W. and Huber, F., 1985; Römer, H. *et al.*, 1988; Boyan, G. S. *et al.*, 1990; Lakes-Harlan, R. and Heller, K.-G., 1992; Jacobs, K. *et al.*, 1999; Nishino, H. and Field, L. H., 2003; Imaizumi, K. and Pollack, G. S., 2005). This region is also the target of many nonacoustic chordotonal organs (Pflüger, J. *et al.*, 1988), suggesting that the conservation of auditory projections reflects the origin of auditory receptors from nonauditory chordotonal organs (Meier, T. and Reichert, H., 1990; Boyan, G. S., 1993).

3.31.2.1.2 Functional organization of central afferent projections

The organization of afferent projections has been studied at fine scale by injecting dye into single physiologically characterized receptor neurons, permitting a detailed histological analysis of axonal projection patterns. Such studies have been performed for only four groups (moths, acridids, tettigoniids, and gryllids) and reveal a functional organization of central projections.

Moths. Three sensory neurons are associated with the ear of noctuid moths. Two of these, designated A1 and A2, are sound sensitive, and the third, the B cell, may serve proprioceptive functions. Retrograde staining of the auditory nerve reveals three axons entering the metathoracic neuromere (Paul, D. H., 1973; Surlykke, A. and Miller, L. A., 1982). Two of these, provisionally identified as A1 and B, have highly similar branching patterns. They bifurcate soon after entering the CNS, projecting axonal branches both anteriorly and posteriorly. The posterior branch arborizes in the metathoracic neuromere as well as in the anterior abdominal neuromeres. Several auditory interneurons have dendritic branches in the same region of the metathoracic ganglion as the branches of A1, providing an anatomical substrate for monosynaptic connections between A1 and the interneurons. The anteriorly directed axons of A1 (and B) also have terminal branches in the mesothoracic neuromere, before coursing further anteriorly through the prothoracic neuromere, where there are no branches, and into the cervical connectives. The central branches of the neuron provisionally identified as A2 are restricted to the mesothoracic and anterior abdominal neuromeres. These branches overlap in some regions with those of A1 and B, but A2 also projects to distinct regions of neuropil.

Only A1 has been identified unambiguously through intracellular staining of the physiologically identified neuron. The identification of A2 was based on comparisons of the anatomy of the neurons, as revealed by retrograde labeling, with the sites in the CNS at which action potentials from A2 can be recorded extracellularly (Surlykke, A. and Miller, L. A., 1982). More recently, it has been suggested that A2 and B may have been misidentified; that is, the neuron with anatomy identical to that of A1 may be A2, rather than B (Lewis, F. P. and Fullard, J. H., 1996).

Acridids. Receptor axons, traveling within the tympanal nerve, enter the metathoracic ganglion complex. Here, some of these form two distinct terminal arbors, one caudal, in the first abdominal neuromere, and one rostral in the anterior metathoracic neuromere. Many receptors axons then continue further anteriorly, arborizing in the mesothoracic and prothoracic ganglia. The sites of these anterior arborizations are segmentally homologous with the rostral termination site in the metathoracic ganglion (Jacobs, K. *et al*., 1999).

Three groups of receptors have been distinguished based on their attachment sites at the tympanic membrane (Figure 1(a)). The groups differ in the probability and extent of arborizations in the central termination sites (Jacobs, K. *et al*., 1999). For example, within the metathoracic ganglion, group I receptors have abundant terminals in the caudal site and relatively sparse terminals in the rostral site. The converse is true for group II, and the majority of group III receptors have no terminals in the caudal site. All group II cells ascend to more anterior ganglia whereas only 60% of group I and 46% of group III receptors have ascending axons.

Histological analysis reveals that, within the rostral neuropil of the metathoracic ganglion, terminals of the three receptor types are anatomically segregated, with group I cells terminating most anteriorly, group II cells most posteriorly, and group III cells sandwiched between these. Because of the differences in frequency tuning between these groups, this arrangement is tonotopic, with low sound frequencies represented anteriorly, and high frequencies posteriorly (Römer, H. *et al*., 1988; (Figure 1(b)).

Tettigoniids. Like the peripheral positions of the cell bodies in the *crista acoustica*, the central projections are tonotopic (Oldfield, B. P., 1983; Römer, H., 1983; Stölting, H. and Stumpner, A., 1998). The gradual shift in frequency tuning from receptor to receptor in the periphery is paralleled by a shift in the positions of their terminal branches in the sensory neuropil within the prothoracic ganglion. The axis of tonotopy is from anterior for low-frequency-tuned receptors to posterior for high-frequency-tuned receptors, with the highest sound frequencies represented dorsally along the posterior edge of the auditory neuropil (Figure 2). In addition, receptors

(b) Axonal arborizations patterns in the prothoracic neuropil, viewed in parasagittal sections, and corresponding tuning curves of identified afferents, anterior (a), ventral (v, c) Branching pattern of three afferents within the prothoracic ganglion, viewed in the horizontal plane. From Stölting, H. and Stumpner, A. 1998. Tonotopic organization of auditory receptors of the bushcricket *Pholidoptera griseoaptera* (Tettigoniidae, Decticinae). Cell Tissue Res. 294, 377–386.

that are tuned to the dominant frequencies of communication signals may have particularly abundant terminal arbors (Oldfield, B. P., 1983), suggesting that the weighting of synaptic inputs to central neurons is uneven across the audible range.

Crickets. Based on the anatomy of their central arborizations, receptor neurons occur as two distinct types. One of these, designated medially terminating (MT), ends with a dense cluster of branches close to the midline. The other, denoted bifurcating (BC), has a characteristic bifurcating terminal arbor which is more lateral and posterior than the terminations of MT-types (Imaizumi, K. and Pollack, G. S., 2005) (Figure 3). Ultrasound-tuned, mid-frequency-tuned, and about half of the receptor neurons tuned to the carrier frequency of the calling song are MT-type; the remaining receptors tuned to the calling song (but none of the mid-frequency or ultrasound-tuned receptors) are BC-type. All of the MT-type receptors project to the same region of the auditory neuropil, where their terminal arbors overlap extensively. The terminal processes of the MT-type afferents overlap

with the dendrites of interneurons that carry acoustic information to the brain (AN1 and AN2 – see further ahead), as well as to a local interneuron (ON1) that modifies ascending information through contralateral inhibition; thus MT-type receptors can provide direct input to these neurons. By contrast, the terminals of BC-type receptors are situated too far posteriorly and laterally to interact substantially with these interneurons. BC terminals do, however, overlap with the dendritic processes of another interneuron, DN1 that relays auditory information to more posterior ganglia, possibly to influence the

thoracic motor output. It thus seems possible that information about calling song stimuli is parsed into separate pathways as early as the level of receptor neurons.

3.31.2.2 Processing and Physiology

By comparison with vertebrates, insect ears are relatively insensitive, with minimum thresholds of receptor neurons sometimes as low as 20 dB SPL, but more typically in the range 30–60 dB SPL. The range of audible frequencies varies widely across species, but seldom extends below 2–3 kHz, and often reaches as high as 100 kHz.

The first step in the neural coding of behaviorally relevant features of acoustic signals, including intensity, pattern of amplitude modulation, and spectral composition, is accomplished by auditory receptor neurons. The transduction machinery (see Chapter 3; Perspectives 7b, 10c) in the scolopidium translates this information into sequences of action potentials in the receptor neurons. Here, we summarize the nature of receptor neuron responses.

3.31.2.3 Coding of Stimulus Amplitude

Auditory receptor neurons respond to sound-induced mechanical oscillations at their attachment site in the ear and transmit series of actions potentials toward the CNS. For comparatively long (>50 ms) acoustic stimuli responses of most receptor neuron are phasi-tonic, that is, spike rate is high at stimulus onset, and after a few tens of milliseconds adapts to a lower level, with spiking continuing for the duration of a long-lasting stimulus. As in most other sensory neurons, increasing stimulus amplitude leads to shorter response latency and higher firing rate. For brief stimuli, firing rate generally increases approximately linearly with increasing sound level (but see Imaizumi, K. and Pollack, G. S., 2001 for exceptions) until saturating, generally at quite high firing rate, for example, 300–500 Hz (Imaizumi, K. and Pollack, G. S., 2001; Benda, J. *et al.*, 2001; Benda, J. and Herz. A. V., 2003; Figure 3(f)). For stimuli lasting longer than 100 ms or so, however, including many communication signals, responses are affected strongly by adaptation, resulting in a flattening of the steady-state intensity–response function as well as an increase in response latency. Moreover, the degree of adaptation depends on the temporal structure of the stimulus (Sippel, M. and Breckow, J., 1984; Givois, V. and Pollack G. S., 2000; Benda, J. *et al.*, 2001). For some stimuli adaptation is sufficiently severe that the time-averaged firing rate loses all value as an indicator of stimulus amplitude.

Another potential code for stimulus intensity stems from the fact that most insect ears contain several sensory neurons that differ in sensitivity. Consequently, the number and identities of receptor neurons for which threshold has been reached changes with increasing stimulus amplitude (Roeder, K. D., 1974; van Staaden, M. J. and Römer, H., 1998; Oshinsky, M. L. and Hoy, R. R., 2002), a coding scheme known as range fractionation. One of the clearest and simplest examples of range fractionation occurs in noctuid moths, which have two auditory receptor neurons per ear, denoted A1 and A2. A1 is the most sensitive of these, with threshold typically in the range 35–55 dB SPL (Fullard, J. H. *et al.*, 2003), but in some species as low as 20–30 dB (Fullard, J. H., 1984b). A2 is about 20 dB less sensitive, reaching threshold at approximately the same stimulus level at which firing rate of A1 begins to saturate (Roeder, K.D. and Treat, A. E., 1957; Madsen, B. M. and Miller, L. A., 1987; Waters, D. A. and Jones, G., 1996).

3.31.2.4 Temporal Coding

Behaviorally relevant stimuli, including communication sounds and sounds produced by predators, are modulated in amplitude through time, establishing the signal's temporal structure, or rhythm. Behavioral tests have shown for a number of insects that temporal pattern is a crucial cue for signal recognition. Stimulus temporal structure must, then, be represented by the responses of receptor neurons. One important temporal feature, the timing of sound-pulse onsets, is accentuated by the receptor population (Nabatiyan, A. *et al.*, 2003), both because of adaptation (see above) and because of synchronized spiking across the receptor population at stimulus onset (Adam, L.-J., 1977; Ronacher, B. and Römer, H., 1985; Pollack, G. S. and Faulkes, Z., 1998).

A recent approach to characterizing the temporal coding properties of receptors utilizes information theory, which allows one to express quantitatively the extent to which the temporal structure of the stimulus amplitude envelope can be recovered from the timing of spikes within a neuron's response (Rieke, F. *et al.*, 1997). Experiments on receptors of grasshoppers (Machens, C. K. *et al.*, 2001, Edin, F. *et al.*, 2004) and crickets (Marsat, G. S. and Pollack, G. P. 2004), show that receptors are broadly tuned

with respect to rates of amplitude modulation, varying only slightly in the accuracy with which they encode modulation rates from *c.* 10 to 100 Hz.

In auditory afferents of grasshoppers, spike rates of 200 Hz appear to be optimal to transmit information about the amplitude modulation of the communication signals to the CNS. Information transfer improves when input from several afferents is combined, saturating at 5–8 afferents (Machens, C. K. *et al.*, 2001). Nevertheless, the spike patterns of single afferents relay sufficient information to allow a reliable discrimination between different song patterns (Machens, C. K. *et al.*, 2003). A particularly salient feature of grasshopper songs, the rapid increase in sound level at the onset of each syllable, is detected by receptor neurons with remarkable temporal precision, with spike-time jitter of as little as 0.15 ms (Rokem, A. *et al.*, 2006). This high precision may play a role in downstream analysis of the syllable-pause structure of the song, which is the key to its recognition by conspecifics (Balakrishnan, R., *et al.*, 2001).

A subset of auditory receptors of the parasitoid fly, *Ormia ochracea*, exhibit properties adapted to the processing of sound pulses produced by their cricket hosts (Oshinsky, M.L. and Hoy, R. R., 2002). These neurons have highly phasic response properties, producing only a single spike at the beginning of a sound pulse. They then require a silent period of at least 4.3 ms before they can spike again. This response property supports synchronous afferent activity at the onset of sound pulses and, moreover, may provide a low-pass filter for pulse repetition rates.

3.31.2.5 Frequency Sensitivity

Early students of insect hearing believed that insects were tone deaf (Pumphrey, R. J., 1940). This view changed in 1960 with the discovery, in a locust (Horridge, G. A., 1960) and in a tettigoniid (Katsuki, Y. and Suga, N., 1960), that different auditory neurons in the same specimen could be most sensitive to different sound frequencies. There are two aspects of frequency sensitivity: (1) frequency *tuning*, that is, variation in sensitivity as a function of frequency and (2) frequency *discrimination*, the ability to respond in different ways to different frequencies independent of stimulus intensity. All auditory systems show tuning to at least some degree, but the capacity for frequency discrimination is more limited.

Sound frequency plays several roles in behavior. First, if an auditory system is sensitive to a restricted range of frequencies that matches the bandwidth of important signals, then extraneous sounds outside this frequency range will not be perceived, thus increasing the signal-to-noise ratio of signal detection. Second, sound frequency can serve as a code for the signal's meaning. For example, crickets are attracted to the low frequency (3–6 kHz) calling song of conspecific males, but they are repelled by ultrasonic (15–80 kHz) bat-like sounds (Moiseff, A. *et al.*, 1978). Indeed, ultrasound elicits avoidance or startle responses in many night-flying insects (Hoy, R. R., 1992). Third, some grasshoppers and tettigoniids determine the sex of a signaling partner in part by the signal's spectrum (von Helversen, D. and von Helversen, O., 1997; Dobler, S. *et al.*, 1994). And a fourth possible role of frequency discrimination is distance estimation. Natural environments act as low-pass filters of sound frequency, with the result that the spectrum of a signal changes as it travels from sender to receiver. Tettigoniids may use this change in spectrum to estimate the distance of a singing conspecific (Römer, H., 1987).

In the following paragraphs we describe the response to and processing of sound frequency by auditory receptors for those insect groups in which this has been studied most thoroughly.

3.31.2.5.1 *Lepidoptera*

In most moths, receptor neurons are tuned rather broadly to ultrasonic frequencies and follow the tuning of the tympanic membrane. Although ears may contain up to four receptor neurons, there is no evidence that these are differently tuned (Roeder, K. D., 1966a; Surlykke, A. and Filskov, M., 1997).

Like moths, nocturnal butterflies have evolved ultrasound-sensitive ears. The presumed sensory organ in this case is Vogel's organ, which is located at the base of the forewing (Yack, J. E. and Fullard, J. H., 1999; Rydell, J. *et al.*, 2003). This consists of three groups of chordotonal organs that are attached directly to the tympanal membrane. In contrast to the usual lepidopteran ear, which contains only a few scolopidia, Vogel's organ may contain 100–200 scolopidia (Yack, J. E. *et al.*, 2000). Vogel's organ has been shown to mediate hearing in some diurnal butterflies as well, in which males produce sounds in interactions with conspecifics (Yack, J. E. *et al.*, 2000). The sounds have peak energy between 8 and 18 kHz.

Neurophysiological recordings have so far been made from only one of the three chordotonal organs,

and peak sensitivity, rather than being in the same range as conspecific signals, is at 1.75 kHz. It remains to be determined whether one of the other chordotonal organs is tuned to the higher-frequency range of conspecific signals. If so, then this would provide the first evidence for frequency discrimination in *Lepidoptera*.

3.31.2.5.2 Acridids

Four groups of receptor neurons were originally identified in the ear of acridids based on the locations of their somata, the attachment sites of their dendrites to the tympanic membrane, response threshold and frequency sensitivity (Gray, E. G., 1960; Michelsen, A., 1971; Römer, H., 1976; Halex, H. *et al.*, 1988). More recent work, in which the physiology, peripheral anatomy, and central projection sites of individual receptor neurons were studied, proposes three functional groups (Jacobs, K. *et al.*, 1999; Figure 1). Group I cells, which number *c.* 20 neurons in *Schistocerca gregaria,* have relatively high thresholds (*c.* 60 dB SPL at the most sensitive frequency), and have two rather broadly tuned regions of best sensitivity: one in the range 400–700 Hz, and the second in the range 1–4 kHz. Cells in group II ($n = 12$–14) are broadly tuned to higher frequencies, ranging from 4–7 kHz to >40 kHz. Sensitivity is greatest in the range 12–25 kHz, with thresholds between 40 and 60 dB SPL. The most populous group, group III with about 40 afferents, is physiologically heterogeneous. Best sensitivity is to frequencies in the range 3–4 kHz, but absolute sensitivity (minimum threshold: 40–60 dB SPL), and breadth of tuning vary widely.

3.31.2.5.3 Tettigoniids

Peripheral discrimination of sound frequency is perhaps best developed in the *crista acoustica* of tettigoniids. Receptor neurons are aligned linearly along the proximo-distal axis of the tibia, reminiscent of the basal-to-apical organization of hair cells within the organ of Corti of vertebrates (see Chapter 6). As in the latter, this organization is tonotopic, with low frequencies represented proximally and high frequencies distally (Oldfield, B. P., 1982; 1984; 1985); Stölting, H. and Stumpner, A., 1998; Figure 2). The auditory organ is attached to the acoustic trachea and has no direct contact to the tympanum. Mapping a frequency range of about 4–50 kHz with wavelength ranging from 82.5 to 6 mm on a less than 1 mm long receptor array probably does not result from pure biomechanics of the auditory trachea but may be due to intrinsic tuning of the receptor cells (Oldfield, B. P., 1985) or to the specific mechanical properties of the accessory structures (dorsal wall, cap cells, tectorial membrane) adjacent to the receptor cells within the *crista acoustica* (Kalmring, K. *et al.*, 1996). The ability of this receptor array to analyze the spectrum of acoustic signals is determined by the number of receptor neurons that are tuned to specific frequencies, the sharpness of their tuning, their absolute sensitivity, and the spacing between their best frequencies. These parameters are often tailored to the spectral composition of behaviorally relevant signals. For example, among three related species, each of which has 25–30 receptor neurons in its *crista acoustica*, the proportions of receptor neurons tuned to low or to high frequencies differ in accordance with the differences in spectral composition of the songs of the species (Kalmring, K. *et al.*, 1993). Adjacent to the *crista acoustica* in bushcrickets (Lin, Y. *et al.*, 1993; Kalmring, K. *et al.*, 1996) lies the bimodal auditory–vibratory intermediate organ which contains about 15 afferents and appears to have a lower auditory sensitivity (Rössler, W. *et al.*, 1994; Stölting, H. and Stumpner, A., 1998).

3.31.2.5.4 Gryllids

As in tettigoniids, auditory afferents of crickets are organized tonotopically within the *crista acoustica* in the tibia (Oldfield, B. P. *et al.*, 1986). Based on structural evidence the *crista acoustica* is divided into three anatomical groups: the proximal group with about ten sensilla, a main group with about 40 sensilla and a distal group with about 10–20 sensilla (Ball, E. E. *et al.*, 1989).

At the single-cell level, the physiology of cricket receptor neurons has been studied most thoroughly in *Teleogryllus oceanicus* (Imaizumi, K. and Pollack, G. S., 1999; 2001). Rather than preferred sound frequency shifting gradually from receptor to receptor, as occurs in the tettigoniids, cricket receptors fall into one of three distinct groups that are most sensitive, respectively, to sound frequencies similar to the dominant frequency of the species' calling song (4–5.5 kHz), to ultrasonic frequencies similar to those used by echolocating bats (>18 kHz), or to an intermediate range of frequencies (9–12 kHz) (Imaizumi, K. and Pollack, G. S., 1999; 2001). The three frequency groups are unequal in size: of the 65–70 receptor neurons in the ear, approximately three quarters fall into the low-frequency group, and one eighth into each of the other two groups (Figure 3(e)).

These three categories are based on responses to sound levels near threshold. When suprathreshold responses are considered, the situation becomes considerably more complicated. Most receptor neurons not only have a particular best frequency, they also have enhanced sensitivity to one or more additional frequencies. Because of these additional sensitivity peaks, the dominant frequency of a stimulus cannot be coded simply by the identities of the activated receptor neurons. Instead, this must be determined by integrating the response magnitudes across the entire receptor population.

3.31.2.5.5 Mantises

A remarkable example of frequency discrimination at the peripheral level occurs in mantises. Many mantises possess an ultrasound-sensitive ear on the midline of the metathorax, which responds best to bat-like sounds (35 kHz) (Yager, D. D. and Hoy, R. R., 1986; Yager, D. D. and May, M. L., 1990). Members of the genus *Creobroter*, however, have an additional, serially homologous ear on the mesothorax (Yager, D. D., 1996). In contrast to the metathoracic ear, the mesothoracic organ is tuned to frequencies in the range 2–4 kHz. Sound production by mantises has not been reported, and as yet the function of low-frequency hearing is unknown.

3.31.2.5.6 Cicadas

The ears of cicadas contain up to 2500 scolopidia. Frequency tuning has not been studied at the level of individual receptor neurons. At the interneuron level, however, different individual cells may be most sensitive to different frequencies, implying that this must be true as well at the receptor-neuron level (Fonseca, P. J. *et al.*, 2000).

3.31.3 Central Pathways

3.31.3.1 Overview

In the central auditory pathway behaviorally relevant information (e.g., sound direction, temporal pattern, or frequency components), is extracted from the afferent spike trains. The first level of central processing occurs within the thoracic auditory neuropil(s). Intersegmental interneurons then forward information to the brain, where adaptive behavioral sequences may be elicited and coordinated via the activation of descending pre-motor interneurons. The properties of the interneurons that accomplish these tasks are shaped by their patterns of connectivity with receptor neurons and with each other, as well as by their intrinsic properties.

As noted above, aspects of early auditory processing, such as the cell biology of receptors and the overall organization of their central projections, are in many ways similar across insect groups. At the interneuron level, however, taxon-specific features become increasingly evident. Here we summarize the general organization of central pathways for those insects in which sufficient information is available. More detailed examinations of specific neural circuits and properties are presented later.

3.31.3.2 Noctuid Moths

Auditory afferents enter the metathoracic neuromere of the fused pterothoracic ganglion and project anteriorly, probably as far as the brain and posteriorly, to abdominal neuromeres, by ascending and descending axonal branches (Surlykke, A. and Miller, L. A., 1982; Lewis, F. P. and Fullard, J. H., 1996). A total of 14 local and ascending interneurons have been characterized in the meta- and mesothoracic neuromeres (Boyan, G.S. and Fullard, J. H., 1986; 1988; Boyan, G.S. and Miller, L. A., 1991; Boyan, G.S. *et al.*, 1990). In each neuromere, some of these receive direct synaptic input from receptors and others are excited polysynaptically. Most interneurons, like the afferents, have local, ascending and descending axonal branches that may interact with motor circuits that drive behavioral responses to acoustic stimulation. The responses of some thoracic neurons resemble those of receptor neurons (these were called repeater neurons by Roeder, K. D., 1966b), but others extract stimulus features such as pulse onset (Roeder's pulse-marker) and repetition rate (Boyan, G.S. and Fullard, J. H., 1986; Boyan, G. S. and Miller, L.A., 1991).

Although auditory interneurons have been recorded in the brain (Roeder, K. D., 1973), cerebral circuits have not been identified. Thoracic processing alone is sufficient to implement some aspects of acoustic behavior. Arctiid moths respond to bat-like stimuli by producing ultrasonic clicks, which appear to interfere with the bat's ability to locate the moth using echolocation (Fullard, J. H. *et al.*, 1994; Ratcliffe, J. M. and Fullard, J. H., 2005). Click generation in response to ultrasound pulses can occur even in moths that have been decapitated. Descending input from the brain does, however, affect the probability and duration of responses (Fullard, J. H., 1982, Dawson J. W. and Fullard J. H., 1995), in agreement with Roeder's (1970; 1973)

speculation that the brain could modulate local auditory reflexes operating in the thoracic ganglia.

3.31.3.3 Acridids

Within the rostral metathoracic and mesothoracic auditory neuropil auditory information is forwarded to local and intersegmental ascending and T-shaped interneurons. Interneurons may project from the metathoracic ganglion to the mesothoracic neuropil or up to the lateral protocerebrum in the brain. Most of the interneurons leaving the meta- or mesothoracic auditory neuropil receive auditory input indirectly, via local and/or bisegmental neurons (Römer, H. and Marquart, V., 1984; Marquart, V., 1985). Descending axons of T-fibers project to motor areas in the metathoracic ganglion.

Surgical manipulations (Ronacher, B. *et al.*, 1986) as well as neurophysiological recordings (Römer, H. *et al.*, 1981; Römer, H. and Marquart, V., 1984; Stumpner, A. and Ronacher, B., 1991; Stumpner, A. *et al.*, 1991) point to the metathoracic auditory neuropil as a site at which important steps in auditory processing take place. This is the site of origin of at least six pairs of local interneurons and 17 pairs of ascending neurons, many of which extract specific features of acoustic signals. For example, some neurons are highly directional but poor at representing stimulus temporal pattern, whereas others have poor directionality but extract particular aspects of temporal pattern, such as the onsets of syllables, their durations, and their continuity. These various snippets of information are presumably integrated in the brain, where the recognition of species-specific song patterns occurs (Bauer, M. and von Helversen, O., 1987). Descending commands from the brain then mediate behavioral responses to acoustic signals, such as song production (Hedwig, B. and Heinrich, R., 1997 and phonotaxis (Ronacher, B. *et al.*, 1986).

3.31.3.4 Ensiferans (Tettigoniids and Gryllids)

Tettigoniids and gryllids are treated together here because the overall organization of early processing appears to be similar in these groups. About 30 (tettigoniids) to 70 (gryllids) afferents enter, and are restricted to, the prothoracic ganglion, where they synapse with local, ascending, and descending neurons. Selectivity of interneurons for sound frequency is established by specific connectivity with receptor neurons as well as by local inhibitory circuits. Local inhibition also plays a role in enhancing the directionality of interneuron responses (Selverston, A., *et al.*, 1985; Horseman, G. and Huber, F., 1994a; Faulkes, Z. and Pollack, G. S., 2000; Marsat, G. and Pollack, G. S., 2005).

A hallmark of this group is that information is carried to the brain by relatively few ascending neurons. In crickets, ascending neurons may number as few as four: two on each side of the midline, with best sensitivity, respectively, to the carrier frequency of the calling song (3–6 kHz) or to higher frequencies such as occur in courtship song of some species (12–16 kHz) and in the echolocation calls of hunting bats (>20 kHz). However, in at least one species of tettigoniid, at least five ascending neurons occur on each side. Unlike the situation in acridids, in ensiferans most ascending neurons are both highly directional and also represent accurately the temporal structures of behaviorally relevant signals (Wohlers, D.W. and Huber, F., 1982; Hennig, R. M., 1988; Marsat, G. and Pollack, G. S. 2004; 2005; Stumpner, A. and Molina, J. 2006).

The ascending neurons provide input to separate networks within the brain for processing of low- and high-frequency signals. Descending neurons carry the results of brain processing back to the thoracic ganglia, where they contribute to the generation of motor responses (Brodfuehrer, P. D. and Hoy, R.R. 1989; Staudacher, E. M., 2001).

3.31.3.5 Sound Frequency

In the following sections we examine how information about sound frequency is processed in the CNS. We focus first on two insect groups, moths and mantises, in which the main role of hearing is to detect the ultrasonic probes of echolocating bats. We then turn to the Orthoptera, where the CNS must deal both with sounds produced by predators, and with intraspecific communication signals.

3.31.3.6 Noctuid Moths

Although some moths use ultrasound signals for intraspecific communication (Conner, W. E., 1999; Sanderford, M. V.. *et al.*, 1998), the earliest function of hearing in this group was probably to detect the ultrasound pulses of echolocating bats, which elicit evasive flight responses (Roeder, K. D., 1962). Hunting bats progress through a series of ultrasound pulse patterns: a search phase, with pulses emitted at relatively low rate, followed by an approach phase,

when pulse rate increases and pulse duration decreases, to the terminal attack phase, when pulse rate may exceed 100 Hz. With natural sequences of bat calls (Fullard, J. H. *et al.*, 2003), escape behavior and defensive sound production (Blest, A. D. *et al.*, 1963; Dunning, D.C. and Roeder, K. D., 1965; Fullard, J. H. *et al.*, 1994) are triggered at the transition between the bat's approach phase and terminal attack phase.

The A1 auditory afferent connects monosynaptically to local and ascending thoracic auditory interneurons (Boyan, G.S. and Fullard, J. H., 1986; 1988). A noise filter at the synapse between the afferent and interneuron 501 appears to prevent escape responses to spontaneous A1 activity and arbitrary sounds. A1 elicits short, rapidly decaying EPSPs in interneuron 501, so that postsynaptic summation reaches threshold only when the spike rate of A1 approaches 250–300 Hz. It has been proposed that this mechanism ensures responses only to bat cries (Boyan, G. S. and Fullard, J.H., 1988).

Evasive behavioral responses are best elicited by ultrasound pulse rates of 25–45 Hz (Roeder, K. D., 1964; Fullard, J. H., 1984a). The neural basis of temporal tuning underlying the avoidance behavior is not completely established. Crucial elements for auditory processing could be pulse marker neurons, which – independent of sound intensity and duration – respond to the onset of sound pulses only (Roeder, K. D., 1966b). Their spike activity will be at maximum at the transition from search to attack calls. Differences across interneurons in the decay times of EPSPs allow differences in sensitivity to pulse repetition rates (Boyan, G. S. and Miller, L. A., 1991). In some interneurons (e.g., 501 and 502) the extended duration of EPSPs leads to temporal summation at approximately 40 sound pulses s^{-1}, whereas in 504, with faster decaying EPSPs, higher repetition rates are necessary (Boyan, G.S. and Fullard, J. H., 1986, Boyan, G. S. and Miller, L. A., 1991). Thus time constants of EPSPs in first-order auditory interneurons may be crucial for the temporal tuning of moth evasive behavior (Figure 4).

3.31.3.7 Mantises

In mantises a prominent interneuron (MR-501-T3) in the metathoracic ganglion appears to mediate ultrasound triggered evasive flight maneuvers, which occur in response to approaching bats (Yager, D. D. *et al.*, 1990; Yager, D. D. and Hoy, R. R., 1989; Triblehorn, J. D. and Yager, D. D., 2005). The neuron

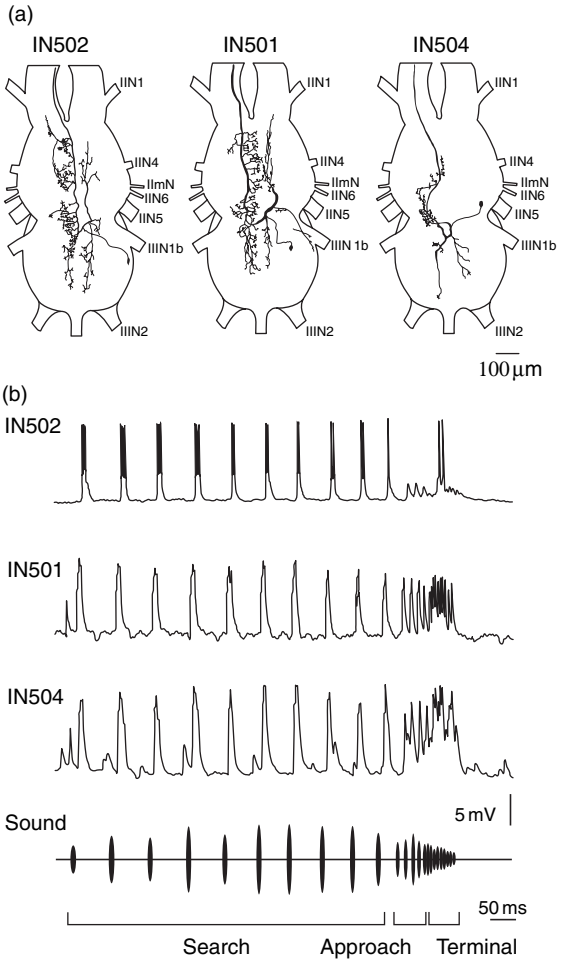

Figure 4 (a) First-order auditory interneurons IN502, IN501, and IN504 in the pterothoracic ganglion of *Heliothis virescens*. Neurons have dendritic branches ipsilateral to the cell body. Axons project within the contralateral connective at least to the prothoracic ganglion and axonal arborisations branch off contralateral to the soma. (b) Intracellular recorded response of the interneurons in *Noctua pronuba* to sound pulses in the call of an echolocating bat, *M. siligorensis* (bottom trace). The call shows a complete sequence containing search (S), approach (A), and the terminal (T) phase. Peak sound level for the pulses with maximum amplitude in the search phase was 80 dB SPL. During the terminal phase the response of IN501 merges to a tonic response whereas IN504 reflects the pattern of the sound due to its faster EPSP decay time. Scale: vertical 5 mV, horizontal 100 µm or 50 ms. (a) From Boyan, G.S. and Fullard, J.H. 1986. Interneurones responding to sound in the tobacco budworm moth *Heliothis virescens* (Noctuidae): morphological and physiological characteristics. J. Comp. Physiol. A 158, 391–404. (b) From Boyan, G. S. and Miller, L. A. 1991. Parallel processing of afferent input by identified interneurons in the auditory pathway of the noctuid moth *Noctua pronuba* (L.). J. Comp. Physiol. A 168, 727–738.

has a large (17 μm) axon that projects anteriorly (Yager, D. D. and Hoy, R. R. 1989) and its structure strongly resembles that of identified, sound-sensitive neurons (the G and B cells) of locusts (Rehbein, H., 1976). Responsiveness to high-frequency sounds (25–60 kHz), fast conduction of spikes (4 m s^{-1}) and reliable high firing rate spike responses to sound pulses repeated even at 60 Hz match the requirements for bat-avoidance behavior (Yager, D. D. and Hoy, R. R., 1989). During live bat attacks, the neuron responds to each sonar pulse of the approaching bat with a high-frequency burst of spikes. The neuron stops responding about 270 ms before contact at the beginning of the terminal phase when the bat homes in on the prey with a series of short sound pulses emitted at more than 100 pulses s^{-1} (Triblehorn, J. D. and Yager, D. D., 2002). Flight evasive responses of the mantis start when pulse repetition rates of the bat reach 20–40 pulses s^{-1}. MR-503-T3 is thus a good candidate for triggering the evasive responses, but a robust electrophysiological test demonstrating the sufficiency of the neuron's activity is not yet available.

3.31.3.8 Acridids

Sound frequency plays several roles in behavioral responses of acridids. Flying locusts exhibit avoidance responses to 30 kHz sound stimuli. Stimuli with frequency of 5 kHz are not effective, and in fact suppress responses to simultaneously delivered ultrasound (Robert, D., 1989). Acridids also use complex sound signals for intraspecific communication. Their songs are generally quite broadband (2–40 kHz), but species-specific and sex-specific spectral differences exist that could contribute to recognition (Meyer, J. and Elsner, N., 1997). A clear role for sound spectrum in communication has been demonstrated in the grasshopper *Chorthippus biguttulus*. Courtship in this species is mediated by an acoustic duet: males emit calling songs, which may evoke a female's response song. If the male recognizes this, he responds with a phonotactic turn and walks toward the female. Both male and female songs have peaks at 5 and *c.* 30 kHz, but high frequencies are more prominent in the songs of males. Tests with female song models show that males respond best with phonotaxis to the low-frequency song components only, and in fact their response is suppressed when high frequencies are added to the model songs, presumably preventing inappropriate approaches to other males (although males will respond with rivalry song to songs of other males). By contrast, females respond best to male song models containing both low- and high-frequency components (von Helversen, D. and von Helversen, O., 1997). Finally, because acridid songs are broadband, and because high frequencies are more strongly attenuated as sound travels through the environment (Römer, H., 1987), the spectrum of the signal at the position of its recipient can, in principle, carry information about the distance to its source.

Auditory receptors of acridids are tuned to either low (<6 kHz) or high (>12 kHz) sound frequencies (see above), and auditory interneurons of the metathoracic ganglion receive direct and/or indirect input from these groups of afferents, with one group (most often the high-frequency afferents) providing mainly excitation and the other providing polysynaptic inhibition. As a result of this mixed input, the responses of the interneurons are quite complex, and often depend strongly on stimulus intensity. For stimuli with broad bandwidth, such as natural songs, the interaction of excitation and inhibition causes many neurons to become intensity tuned, that is, they respond maximally to a particular intensity range (Römer, H. and Marquart, V., 1984; Römer, H. and Seikowski, V., 1985). Thus intensity coding through frequency-specific inhibition may be an additional function of frequency discrimination in acridids.

The mixture of excitatory and inhibitory input to most interneurons also shapes the temporal structure of their responses. For example, low-frequency-induced inhibition precedes excitation in the neuron AN2, increasing its response latency. In AN1, by contrast, inhibition is delayed, causing the neuron's response to be phasic.

The sources of low-frequency-tuned inhibition include the identified interneuron, SN1 (Marquart, V., 1985) and, probably, another identified neuron, TN1 (Sokoliuk, T. *et al.*, 1989). A population of GABA-immunoreactive neurons, with somata at the dorsal midline and processes in the auditory neuropil, comprises another set of candidates (Thompson, K.J., and Siegler, M. V. S., 1991). Although these neurons are sound sensitive, their auditory characteristics (e.g., thresholds, best frequencies) have not been described.

3.31.3.9 Tettigoniids

Sound frequency is important in a number of behavioral contexts, distinguishing the songs of different species (Keuper, A. *et al.*, 1988), of different genders (Dobler, S. *et al.*, 1994), and even of different

individuals (Latimer, W. and Sippel, M., 1987). Tettigoniids, like acridids (and gryllids, see below) also respond to bat-like ultrasound signals by negative phonotaxis, interruption of flight, and cessation of singing (Libersat, F. and Hoy, R. R., 1991; Faure, P. A. and Hoy, R. R., 2000a; Schultz, W. and Schul, J., 2001). The sophisticated frequency-discrimination capabilities of the array of receptors in the tettigoniid ear (see above), together with their tonotopic projections to the CNS, provide the basis for central frequency processing.

The initial stage of frequency processing in the CNS is established by the patterns of connectivity between receptor neurons and interneurons. This in turn is determined by the positions, within the tonotopic receptor projection, of the interneurons' dendrites. The Omega neuron of *Tettigonia viridissima* has dendritic processes that are coextensive with the entire projection area of receptors, except for a small anterior region, which is the target area of low-frequency-tuned receptors. Accordingly, frequency sensitivity of the Omega neuron matches that of the entire auditory nerve except for low frequencies, where Omega is comparatively less sensitive. Similarly, a descending neuron in *Mygalopsis marki,* with dendrites that are restricted to the anterior, low-frequency, portion of the receptor projection, responds only to low frequencies (Figure 5).

Although specific connectivity does impart a degree of frequency selectivity, many interneurons clearly receive convergent input from a large number of differently tuned receptor neurons, with the result that the relatively fine-scaled frequency tuning available at the periphery is lost. Tuning of auditory interneurons may, however, be recovered through frequency-specific inhibition. In a group of related species in the subfamily *Phaneropterinae*, an ascending neuron, AN1, has frequency tuning that matches the spectrum of communication signals. AN1's tuning is species-specific, in contrast to the Omega neuron, the tuning of which is indistinguishable between the species (Stumpner, A., 1997; 2002). AN1's dendrites, like those of the Omega neuron, are widespread throughout the auditory neuropil, suggesting that specific connectivity cannot account for the difference in tuning of these two neurons. Intracellular recordings show that AN1 receives frequency-specific inhibitory inputs. When these are blocked pharmacologically, the species-specific differences in tuning disappear. Thus inhibition, rather than excitation, accounts for the species-specific difference in tuning of this neuron.

Another function of frequency-tuned neurons may be to facilitate distance estimation. The spectrum of tettigoniid songs typically extends from a few kHz into the ultrasonic range. However, as the sound

Level of histological sections of the neurons indicated by the stippled line in the whole-mount drawings. (c) Correlation between the dendritic branching pattern and broad or narrow frequency tuning of the interneurons. Tuning of the interneurons (dots, solid line) is compared with the tuning of the ears as measured by recordings of the whole auditory nerve (dashed line). Ordinate: threshold sound level (dB SPL); abscissa: sound frequency (kHz). From Römer, H., Marquardt, V., and Hardt, M. 1988. Organisation of a sensory neuropile in the auditory pathway of two groups of Orthoptera. J. Comp. Neurol. 275, 201–215.

signal travels through the biotope its spectrum changes, with high-frequency components being attenuated more severely than low-frequency components. As a consequence, the identities of the receptors that are activated, and their degree of activation, could provide information on the distance of the signaler. Depending on the signal spectrum as emitted by the sender, different groups of receptors will be able to track the signal over different ranges of distance. For example, one group might just be reaching threshold at distances where another group begins to saturate. Thus, frequency tuning of the afferents implements a form of range fractionation for signal distance. In *Mygalopsis marki*, receptors that are tuned to low (4–6 kHz) or high (>28 kHz) frequencies respond best over close ranges, the former because the signal emitted by the male contains relatively little power at low frequencies, and the latter because of the severe attenuation of high-frequency components. Receptors tuned to intermediate frequencies (10–20 kHz) operate over longer distances (Römer, H., 1987; Figure 6(a)–(e)). Moreover, the tonotopic organization of receptors translates this relationship between receptor tuning and distance into an odotopic map; the locus of activity within the auditory neuropil shifts systematically with the distance from the sound source (Figure 6(f)). As discussed above, different interneurons sample different regions of this neuropil, and thus differences in operating range occur at the interneuron level as well. For at least one class of interneuron (possibly homologous with AN1, described above), range selectivity is enhanced by frequency-specific inhibition. This results in range-tuned neurons, for which response is maximal for signals arising from a particular distance.

A large, T-shaped interneuron (Suga, N. and Katsuki, Y., 1961; Kalmring, K. *et al*., 1979; Oldfield, B. P. and Hill, K. G., 1983) has been most closely associated with ultrasound-elicited evasive responses. In *Neoconocephalus ensiger* the lowest threshold (30–40 dB SPL) occurs at 20–25 kHz with sensitivity extending to 100 kHz (Faure, P. A. and Hoy, R. R., 2000b). The tuning curve closely matches the tuning of the evasive behavior (Faure, P. A. and Hoy, R. R., 2000a), however, the threshold of the T-fiber is 15–20 dB lower. The neuron responds more strongly to bat-like high-frequency pulses (30 kHz) than to sound pulses with the dominant frequency (15 kHz) of the *N. ensiger* song (Libersat, F. and Hoy, R. R., 1991). Temporal coding of repetitive sound signals is reliable up to 30 pulses s^{-1} for short (10 ms) constant frequency (40 kHz) or frequency modulated (80→30 kHz) bat-like signals. In contrast responses to patterns mimicking the conspecific calling song (12–15 kHz, 30 ms) fail at 5–10 Hz repetition rate (Faure, P. A. and Hoy, R. R., 2000b; 2000c). Also the response latency is shorter (13 ms) for bat-like sounds than for calling song signals (18 ms). This evidence indicates a functional role for the T-fiber in ultrasound mediated startle responses. However, the same neuron has also been proposed to play a role in intraspecific communication in the genus *Tettigonia* (Schul, J., 1997).

3.31.3.10 Gryllids

Male crickets produce calling songs to attract females, and aggression songs in interactions with males. The songs are relatively sharply tuned, with most power at the fundamental frequency, which for field crickets is typically in the range 3–6 kHz. A third signal, courtship song, is emitted when male and female come into contact and elicits a mounting response in females, a prerequisite for mating. In many species courtship song contains sound pulses of two spectral types: a low-amplitude pulse dominated by the fundamental frequency, and an intense pulse dominated by its third harmonic, whereas in other taxa (e.g., *Teleogryllus*) courtship song is spectrally similar to calling song. The importance of song spectrum for behavioral function has been demonstrated in a number of behavioral studies. For example, attraction of females is tuned to the fundamental frequency component of the calling song (Hennig, R. M. and Weber, T., 1997), although the addition of higher harmonics improves both attractiveness and accuracy of localization (Latimer, W. and Lewis, D. B., 1986). Mounting responses during courtship are also best elicited by the dominant frequency of the courtship song (Balakrishnan, R. and Pollack, G. S., 1996; Libersat, F. *et al*., 1994). In addition, crickets are sensitive to ultrasonic frequencies (20–40 kHz) similar to those produced by echolocating bats. Stimulation with ultrasound elicits avoidance responses (Moiseff, A. *et al*., 1978; Pollack, G. S. *et al*., 1984; Nolen, T. G. and Hoy, R. R., 1986a).

Although three frequency ranges are represented peripherally (see above), in the CNS neurons are generally tuned either to a low-frequency range, centered on the dominant frequency of calling song, and/or to a broad, high-frequency range that includes the frequencies that occur in courtship song (for some species) and bat calls. Most attention has focused on neurons that carry auditory information from the prothoracic ganglion to the brain and on local,

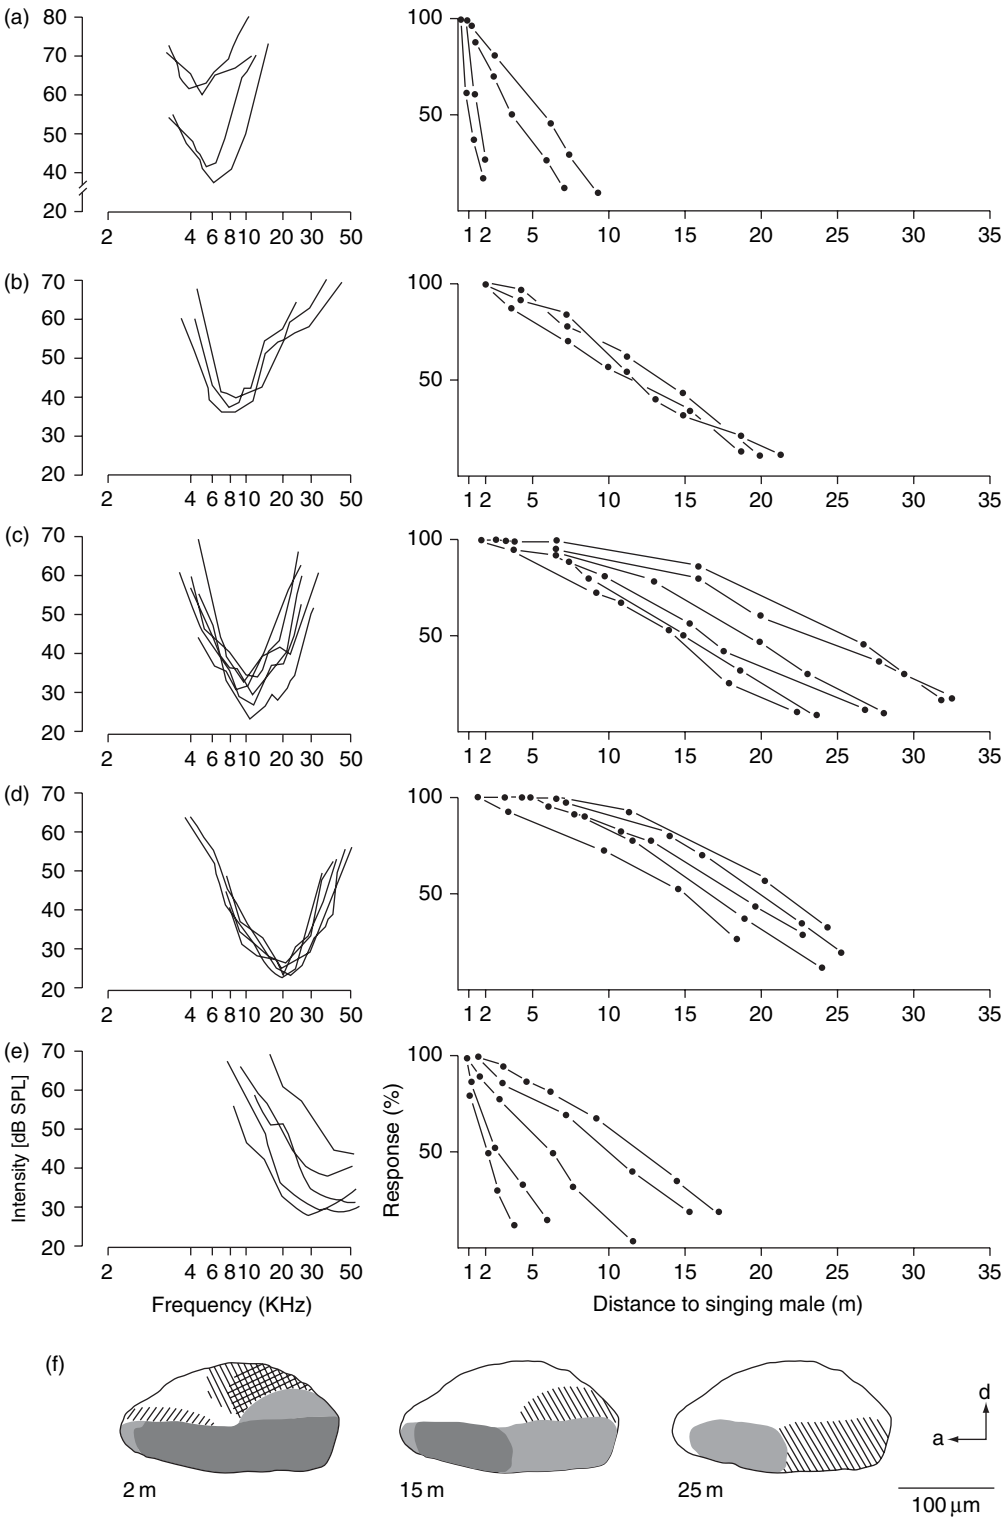

Figure 6 Representation of distance by auditory afferents in *Mygalopsis marki*. (a – e) Tuning curves (left) and distance response characteristics (right) of 26 auditory afferents with optimum frequencies of 4 and 6 kHz (a), 8 kHz (b), 10–12 kHz (c), 20 kHz (d), and above 28 kHz (e). The response magnitude is given as a percentage of the maximum number of spikes/song. Note that whereas all of the receptors are active for nearby sources, activity of the different groups drops off with distance at different rates. (f) Schematic representation of the spatial distribution of receptor fiber activity within the neuropil at three different distances (2, 15, and 25 m) to a calling male. Dark area indicates the relative amount of afferent activity. At intermediate distances dorsal areas also start to be activated. anterior (a), dorsal (d). From Römer, H. 1987. Representation of auditory distance within a central neuropile of the bushcricket *Mygalopsis marki*. J. Comp. Physiol. A 161, 33–42.

prothoracic neurons that shape this information. As described below, manipulation of neural activity in behaving animals has revealed the functional roles of some of these interneurons. Other interneurons, with axons descending from the prothorax to posterior ganglia, and with both ascending and descending axons, have also been described but their roles in behavior are less clear.

There is some disagreement about the number of ascending neurons. Some workers report two on each side (left or right) of the prothoracic ganglion, one, denoted AN1, that is sharply tuned to the calling-song fundamental, and another, AN2, with broad tuning to high frequencies (Wohlers, D. W. and Huber, F., 1982; Hennig, R. M., 1988). Others report a third ascending neuron, but without agreement on its physiological properties (Atkins, S. *et al.*, 1989; Boyd, P. *et al.*, 1984).

The roles of AN1 and AN2 in frequency-specific behaviors have been demonstrated by manipulating their activity in behaving animals (Schildberger, K., 1994; Nolen, T. G. and Hoy, R. R., 1984). When one of the AN1s of *Gryllus bimaculatus* is hyperpolarized (and thus silenced) while a cricket tracks a calling song model by walking on a spherical treadmill, the cricket turns toward the other side, no matter from which side the song is played (Schildberger, K. and Hörner, M., 1988; Figure 7). Similarly, destruction of L1, the presumed homolog to AN1 in *Acheta domesticus,* results in deviation and circling toward the intact side, and phonotaxis stops when this ear is blocked (Atkins, G. *et al.*, 1992). Thus, information about low-frequency stimuli carried to the brain by AN1 and L1 is clearly behaviorally relevant.

AN2 is most sensitive to high sound frequencies and participates in bat-avoidance responses of flying crickets. When AN2 is hyperpolarized while a cricket performs tethered flight, avoidance responses to ultrasound stimuli played from the same side are abolished. When AN2 is caused to fire at high frequency by release from hyperpolarization, an avoidance response occurs, even though no sound is played. These links between AN2 and behavior are operational only when the cricket is flying. High-firing-rate activity of AN2, whether elicited by release from hyperpolarization or by sound, is not accompanied by a behavioral response in quiescent animals. Thus, AN2's activity is both necessary and sufficient for the response, so long as the cricket is actively flying (Figure 8). Crickets also perform negative phonotaxis while walking (Pollack, G. S. *et al.*, 1984). It is not yet known whether AN2 plays any role in this behavior.

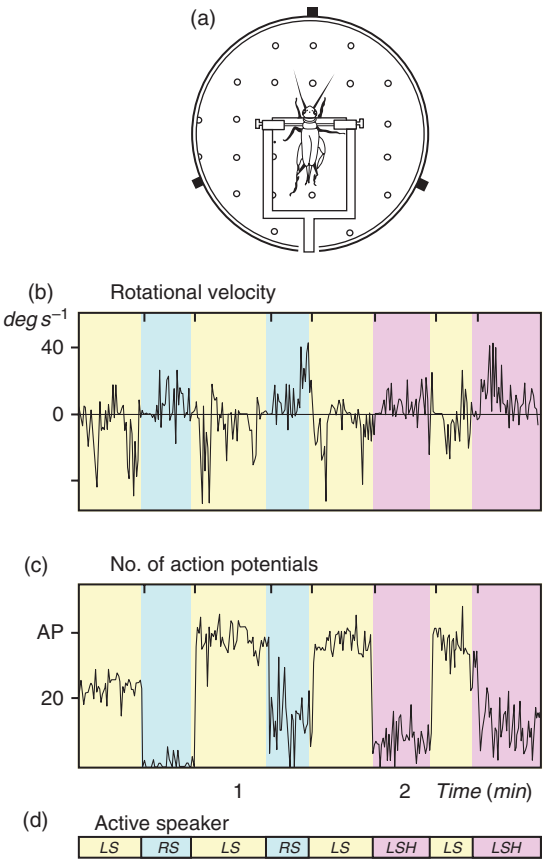

Figure 7 Role of an identified interneuron, AN1, in phonotaxis. (a) The cricket was tethered to a holder in a manner that permitted it to walk on the surface of an air-supported sphere, while AN1 was impaled with a microelectrode to record and manipulate its activity. Walking direction was monitored by tracking the movements of the sphere. (b) Rotational velocity of the sphere; positive rotational velocity indicates turns to the right, and negative velocity indicates left turns. (c) Spike rate of the left AN1. (d) Indicator of experimental conditions. During the time periods indicated by yellow shading, a calling-song model was played from the left side, resulting in firing of AN1 and turns to the left. During the periods indicated with cyan shading, the sound was played from the right; spike rate in left AN1 was low, and the cricket turned right. The crucial periods are indicated with magenta shading; sound was played from the left, but the left AN1 was hyperpolarized, decreasing its spike rate; the cricket turned right. Adapted from Schildberger, K. and Hörner, M. 1988. The function of auditory neurons in cricket phonotaxis I. Influence of hyperpolarization of identified neurons on sound localisation. J. Comp. Physiol. A 163, 621–631.

AN2 elicits behavioral responses only if it fires at high rate (Nolen, T.G. and Hoy, R. R., 1984). For continuous dynamic stimulation with ultrasound, as

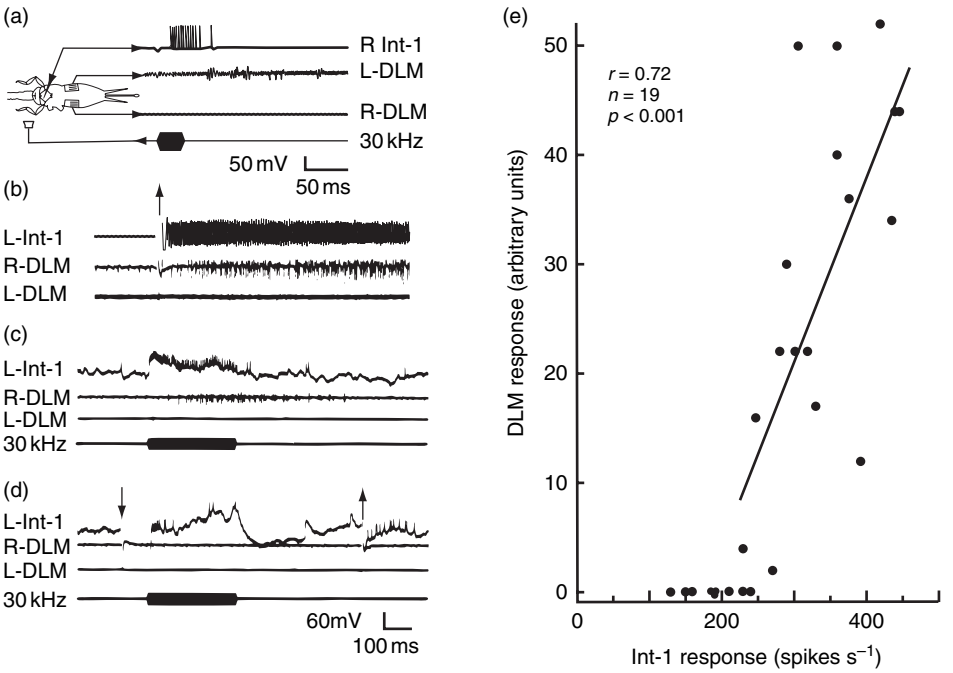

Figure 8 Effect of Int-1 (=AN2) on flight steering in *Teleogryllus oceanicus.* (a) Preparation for simultaneous recordings of Int-1, abdominal dorsal-longitudinal flight-steering muscle activity (DLM), and acoustic stimulation with 30 kHz, 85 dB SPL, 30 ms at 90° to the animal's length axis. A sound pulse elicits a burst of spikes in the left Int-1 and a burst of activity in the right DLM, indicating an attempt to steer to the right. (b) Release of the left Int-1 from hyperpolarizing current injection with −8 nA elicits a spike rate of 400 Hz and causes a steering response in the right DLM. (c) A sound stimulus (30 kHz, 300 ms, 82 dB SPL) presented to the left ear elicits a steering response. (d) When Int-1 is hyperpolarized with −15 nA, its spike activity during acoustic stimulation is reduced to less than 170 Hz and the steering response is suppressed. Duration of current injection is indicated by arrows. (e) Relation between Int-1 spike activity and activity of the steering muscle. Muscle activity correlates with Int-1 spike rates above 230 Hz. might occur under natural conditions, AN2 produces brief bursts of high-frequency firing following sharp increases in sound amplitude. The bursts follow these important stimulus features reliably and, moreover, they reliably encode the sound-source direction through binaural differences in bursting. By contrast, isolated spikes of AN2, which also occur in the responses, perform poorly at both tasks. And, as expected from the work of Nolen and Hoy, bursts, but not isolated spikes, elicit avoidance responses (Marsat, G. and Pollack, G. S., 2006).

Both AN1 and AN2 terminate in the brain. Auditory processing here involves local neurons with arborizations restricted to the brain as well as intersegmental neurons with axons that descend to the thoracic ganglia, where they may mediate motor responses to sound. Within both types, there are neurons that are tuned to the calling-song frequency, and others that are most sensitive to high-frequency sounds (Boyan, G. S., 1980; 1981; Schildberger, K., 1984; Brodfuehrer, P. D. and Hoy, R. R., 1990).

The separation of low- and high-frequency processing has its origins in the properties of receptor neurons, but is enhanced through central inhibition. High-frequency-tuned interneurons, both in the prothorax and in the brain, are inhibited by simultaneous low-frequency stimuli (Moiseff, A. and Hoy, R. R., 1983; Nolen, T. G. and Hoy, R. R. 1986a; Boyd, P. *et al.*, 1984; Boyan, G. S. 1980;1981). In those species in which the courtship song includes higher harmonics, inhibition of the high-frequency pathway by low-frequency stimuli would prevent inappropriate activation of putative courtship-song-detecting circuits by the higher harmonics of calling song (Boyan, G. S., 1981). In species that exhibit negative phonotaxis to ultrasound, low-on-high inhibition would prevent inappropriate avoidance of a calling male (Nolen, T.G. and Hoy, R. R., 1986b). Another possible function of this inhibition is to restrict the responses of high-frequency-tuned interneurons to the middle of their dynamic range, thus preventing response

saturation. This would allow the neurons to track the stimulus temporal pattern over a wide range of intensities (Hutchings, M. and Lewis, B., 1984).

3.31.3.11 Temporal Processing and Pattern Recognition

Acoustic signaling for mate attraction requires the identification of the species-specific song pattern by the receiver. In behavioral experiments pattern recognition can only be analyzed through an observable reaction in the receiving animal (Alexander, R. D., 1967; Weber, T. and Thorson, J., 1989). Generally, the singing response or phonotactic orientation of the receiver is used as an indicator to explore the tuning of the recognition process and to elucidate underlying neural mechanisms. Additional complexity may be added by the interaction of recognition and localization, since the underlying neural mechanisms need to be separated in space and/or time. Pattern recognition may benefit from summing the afferent responses of both ears, whereas localization and steering depend on the difference between both signals, which requires their comparison, either prior to the generation of steering commands (von Helversen, D., 1984; von Helversen, D. and von Helversen, O., 1990), or at the level of the motor output (Stabel, J. *et al.*, 1989). Crucial information about pattern recognition has been obtained from behavioral and neurophysiological evidence. Peripheral specializations allow frequency filtering of the species-specific signals, but the final task of identifying the species-specific signal is accomplished in the CNS and in particular the brain (Bauer, M. and von Helversen, O., 1987). Neural mechanisms underlying pattern recognition are best analyzed in crickets and acridid grasshoppers. Only little information is available on cicada, katydids, moths, and other groups.

3.31.3.12 Pattern Recognition in Grasshoppers

Acridid grasshoppers (*Gomphocerinae*) produce broad-frequency (2–40 kHz) sound signals (Meyer, J. and Elsner, N., 1996) by rubbing the hind legs against the wings. Signal amplitude is initially low and may increase to a maximum of 60–66 dB SPL in males (at 10 cm distance, von Helversen, O. and von Helversen , D., 1994). Songs last for several seconds and are characterized by a species-specific pattern of amplitude modulation, that is, sequences of sound pulses and pauses, which are grouped into subunits (syllables). Signals are different in males and females (von Helversen, D. and von Helversen, O., 1997) and are crucial for intraspecific communication and mate attraction. Studies of pattern recognition and orientation have especially focused on the group of *Chorthippus* species (von Helversen, D., 1997).

The general organization of pattern recognition is well characterized (von Helversen, D., 1997) but specific details are not yet understood. From the ears about 60 auditory afferents (Pauls, S. *et al.*, 2001) forward auditory information to the metathoracic ganglion. But the afferent activity does not provide a filter for species-specific signal features (Römer, H., 1976). A crucial step occurs at the first level of auditory processing. In the recognition pathway, which is separate from the processing of sound direction (see below), the afferent information of both ears is merged. Split-song sound patterns (i.e., different song components presented to each ear) that are not effective when presented by their own to one ear, release a behavioral response when the complete pattern is reconstructed by presenting some components to one ear and the remainder simultaneously to the other ear (von Helversen, D., 1984; 1997); thus, input from both ears can be combined prior to pattern recognition. Micro lesions of the thoracic connectives point to the metathoracic ganglion as the location of auditory summation (Ronacher, B. *et al.*, 1986). In the metathoracic ganglion at least six types of local interneurons and at least 17 different ascending interneurons receive afferent information and forward their spike trains to the brain (Stumpner, A. and Ronacher, B., 1991) where they terminate in the lateral protocerebrum (Rehbein, H., 1976; Hedwig, B., 1986). Most of these ascending neurons exhibit poor directionality and show different degrees of phasic, tonic, excitatory, and inhibitory responses. The interneurons differ in details of their activity patterns and seem to forward different features of the sound signal to the brain; however, none appears to be particularly tuned to the species-specific song pattern (Stumpner, A. *et al.*, 1991). More specific functions may be assigned to the interneuron AN4, which is involved in gap detection (see below) and to AN12, which phasically responds only to the onset of syllables (Stumpner, A. *et al.*, 1991). Pattern recognition is located in the brain (Bauer, M. and von Helversen, O., 1987). A central question is whether the animals use the repetitive song structure to integrate auditory information over time or whether they rely on real time processing based on parallel auditory information provided by the ascending interneurons. Songs of *Ch.*

biguttulus females last for 1–1.5 s and are composed of 12 subunits. However, under ideal auditory conditions – with subunits presented at maximum natural amplitude – pattern recognition by males is achieved within just 250 ms by processing only three subunits (Ronacher, B. and Krahe, R., 1998). Thus pattern recognition does not require a long-term sampling strategy but rather is a real-time analysis (Ronacher, B. *et al.*, 2004). Obviously the cross fiber pattern of the numerous ascending neurons provides the information for a rapid identification of the species-specific signal. A model for feature extraction from the species-specific pattern of amplitude-modulated sound has been proposed (Balakrishnan, R. *et al.*, 2001). The model is based on a syllable onset detector, a filter for the syllable periods and a syllable pause detector. So far only some general physiological responses of brain neurons have been characterized in the locust (Römer, H. and Seikowski, U., 1985). The large number of ascending auditory neurons and the unknown recognition network in the brain may allow for subtle changes in cellular and network properties corresponding to receiver variability and species-specific pattern recognition, which has to match intraspecific signal variation and the diversity of *Gomphocerine* songs.

3.31.3.12.1 Gap detection

Songs of acridid grasshoppers are generated by the movements of the hind legs, each scratching a row of cuticular pegs against the front wings. Calling songs of *Ch. biguttulus* males are composed of sequences of amplitude modulated broadband noise of 2–3 s duration. The legs move slightly out of phase, so that the brief silent intervals of 2–3 ms duration (gaps) that occur at the transitions between upward and downward movements of a single leg are filled in by sound produced by the other leg. The loss of one hind leg reveals these gaps within the syllables of a song (von Helversen, D., 1972; von Helversen, O., 1979). When *Ch. biguttulus* females are exposed to male songs with gaps ranging from 0 to 4 ms their response is gradually abolished (von Helversen, D., 1972; Ronacher, B. and Stumpner, A., 1988). Mating success of males having only one hind leg is reduced by 87.2% (Kriegbaum, H., 1989), demonstrating a strong preference of females for the calling song of intact males. Although the spike pattern of individual auditory afferents cannot resolve the gaps, spike synchronization over the population of 60–80 afferents is sufficient to forward the occurrence of silent intervals to the CNS (Ronacher, B. and Römer, H., 1985). Gaps have no effect on the responses of most ascending auditory interneurons, but they drastically affect that of interneuron AN4. This neuron receives pronounced IPSPs at the onset of a sound pulse followed by synaptic excitation during the tonic sound component. In response to a continuous sound (i.e., gap-free pulses) AN4 therefore spikes after an initial transient inhibition; but its spike response is completely suppressed when short silent gaps consecutively re-trigger the inhibition. The decay of AN4's spike response closely matches the decay of the female behavior for increasing gap duration (Ronacher, B. and Stumpner, A., 1988). In *Ch. biguttulus* this property of AN4 appears to be involved in efficient selection against males that have lost one hind leg. Since female responses are suppressed when AN4 is not spiking, activity of this neuron may be essential to activate the calling-song recognition network in the brain (Figure 9).

3.31.3.13 Gryllids

Cricket calling songs are characterized by high-intensity sound pulses ranging from 6 to 50 ms duration which are arranged in long lasting sequences of pulses, or grouped in chirps and intermittent silent intervals, or organized in alternations of chirps and trills with different pulse rates (Alexander, R. D., 1961). Since the carrier frequency of the signal shows little modulation, far-field recognition of the male's calling song depends on the temporal structure of the pulse pattern. Behavioral experiments point to the pulse rate as the most important character for pattern recognition (Zaretsky, M. D., 1972; Thorson, J. *et al.*, 1982). Phonotaxis is maximum at the species-specific pulse rate and decreases at higher and lower rates. Other song features, such as pulse duration, pulse duty cycle, and the organization of pulses into higher-order structures such as chirps and trills, can also influence the phonotactic response (Doherty, J. A., 1985; Stout, J. F. and McGhee, R., 1988; Pollack, G. S. and Hoy, R. R., 1979; Hennig, R. M. and Weber, T., 1997; Hennig, R. M., 2003).

Phonotaxis during flight (Pollack, G. S. and Hoy, R. R., 1981) and during walking on a sensitive trackball system (Hedwig, B. and Poulet, J. F. A., 2004; 2005) demonstrated fast reflex-like steering movements toward individual sound pulses that underlie the orientation behavior. The females also steer toward nonattractive pulses if these are inserted into a sequence of the calling song. The amplitude of steering responses gradually increases at the start

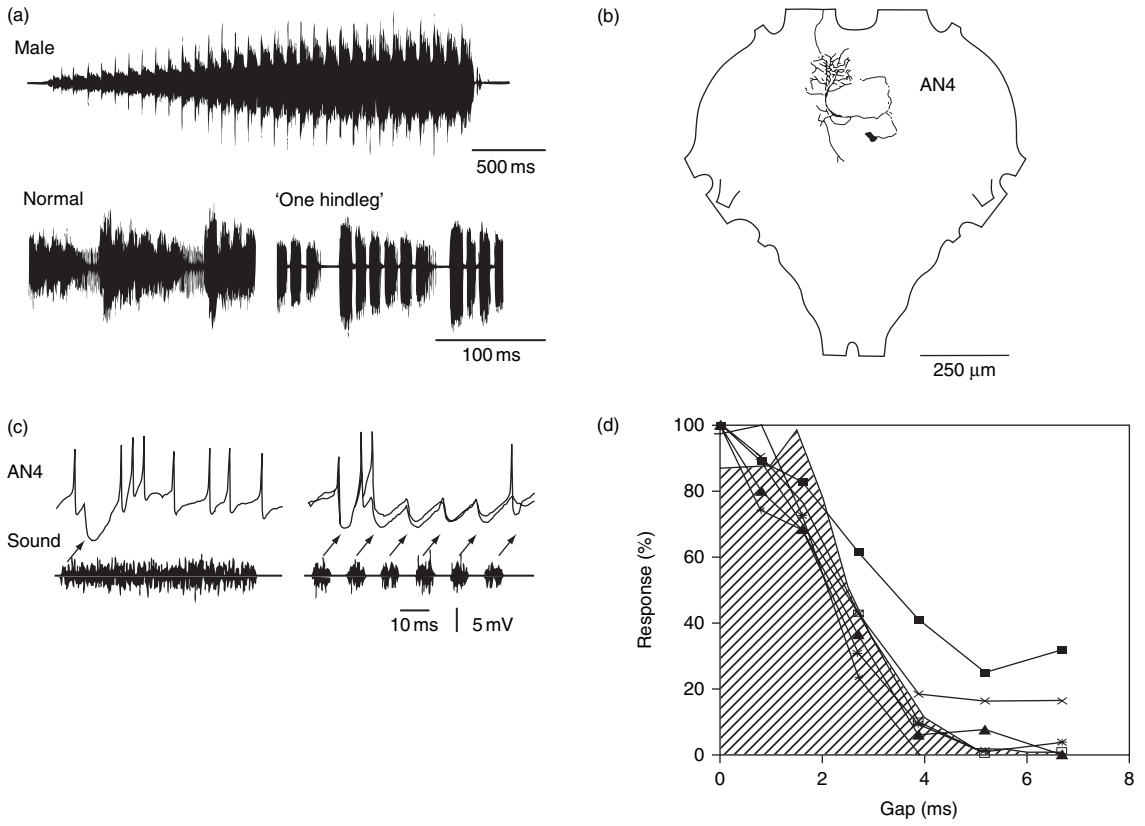

Figure 9 Detection of silent gaps in the song of a grasshopper. (a) Normal song of a male grasshopper *Chorthippus biguttulus* (top). Section of a normal song at higher temporal resolution (lower left) and of a song produced with one hind leg only (lower right). (b) Structure of the ascending auditory interneuron AN4 in the metathoracic ganglion. Main dendritic branches are located in the rostral auditory neuropil, the axon projects to the brain. (c) Intracellularly recorded response to acoustic stimulation with a normal conspecific syllable (left) and with a syllable interrupted by silent gaps (right). Two recordings are superimposed on the right. Each sound onset triggers a pronounced IPSP. (d) Relative response of four AN4 interneurons to syllables with different gap durations at intensities between 66 and 78 dB SPL. The relative behavioral response toward the sound stimuli with increasing gaps is based on three females and indicated by the shaded area. From Stumpner, A. and Ronacher, B. 1994. Neurophysiological aspects of song pattern recognition and sound localization in grasshoppers. Amer. Zool. 34, 696–705.

of phonotaxis and the response to nonoptimal test pulses decreases over several seconds after a sequence of phonotaxis (Poulet, J. F. A. and Hedwig, B., 2005; Hedwig, B. 2006). These results indicate that the pattern recognition process modulates the gain of auditory steering and that pattern recognition itself is not directly involved in the fast steering responses. This modulation appears to be mediated by the brain, since phonotactic steering fails after the brain has been disconnected from the CNS (Pollack, G. S. and Hoy, R. R., 1981).

Various possible mechanisms for pattern recognition have been discussed, including template matching (Hoy, R. R., 1978; Pollack, G. S. and Hoy, R. R., 1979), cross- and autocorrelation (Weber, T. and Thorson, J., 1989; Hennig, R. M., 2003), band-pass filtering (Schildberger, K., 1984), and instantaneous discharge rate coding (Nabatiyan, A. *et al.*, 2003), and some neurobiological evidence relates to the filtering of the syllable rate. Afferents respond with phasi-tonic spike patterns to acoustic stimuli. At the population level the synchronous activity of the afferents leads to a strong onset response highlighting the onsets of sound pulses (Nabatiyan, A. *et al.*, 2003), possibly facilitating downstream measurement of pulse rate. The time constant of mutual inhibition between the local thoracic ON1 neurons has been proposed to constitute a temporal filter matched to the species-specific syllable rate (Wiese, K. and Eilts-Grimm, K., 1985), but Marsat G. and Pollack G. S. (2004) found no change in ON1's temporal coding properties when the contralateral neuron was deafferented. The ascending

thoracic interneurons of crickets, AN1 and AN2, are not selective for temporal patterns if only their spike numbers are considered. They respond to different types of pulse patterns with the same mean spike rate and appear to copy and forward a wide range of patterns to the brain (Wohlers, D.W. and Huber, F., 1982; Huber, F., 1983). However, when the coding properties of the neurons are analyzed using an information-theoretic approach, ON1 and AN1 in *Teleogryllus oceanicus* code best for amplitude modulations in the range 5–30 Hz, corresponding to the range of modulation rates which occur in the species' songs (Marsat, G. and Pollack, G. S., 2004; 2005). If the instantaneous spike rates are analyzed in response to different syllable rates, ON1 generates a maximum number of high-frequency discharges (200–300 Hz) at the species-specific syllable period. This indicates thoracic filtering of the species-specific pulse rate. The activity of any postsynaptic neuron that is driven by such a spike pattern will exhibit band-pass characteristics, like the tuning of phonotactic behavior (Nabatiyan, A. *et al.*, 2003). Boyan, G. S. (1984) provides evidence for local brain neurons clearly responding to the pattern of the calling song. The activity of other local brain neurons, some with rather weak auditory responses, has been interpreted to support a concept that pattern recognition is based on a series of low-pass and high-pass filters which in combination lead to a band-pass filter for the syllable rate (Schildberger, K., 1984). The arborization patterns of all local auditory brain neurons are restricted to one side of the brain only (Boyan, G. S., 1980; Schildberger, K., 1984). Since the ascending auditory information is also strictly side-specific, two separate recognition systems may exist, one located in each half of the brain (Pollack, G. S., 1986). The functional properties of these recognition networks still have to be elucidated.

3.31.3.14 Tettigoniids

Phonotaxis behavior and its neural correlates have also been analyzed in a group of closely related Tettigoniids (Schul, J., 1997; Schul, J. *et al.*, 1998;, Schul, J., 1998) where males attract females by series of sound pulses comprising low (8–12 kHz) and high carrier frequency (25–45 kHz) components. In one species (*T. cantans*) pattern recognition is based on a pulse-rate mechanism, whereas *T. caudata* uses the detection of a minimum duty cycle. The species *T. viridissima* has a more complex recognition system based on pulse duration and the interval between double-pulses. Interestingly in two species (*T. caudata* and *T. viridissima*) the pulse structure of the songs are more elaborate than the requirements of the pattern recognition system (Schul, J., 1998).

The central auditory pathway in tettigoniids shares common features and homologous neurons with crickets. Ascending auditory neurons (AN1, AN2) and T-shaped interneurons copy the pulse structure of the song and forward this information to the brain. The T-fiber has been implicated in pattern recognition (Schul, J., 1997); however, it responds best to high sound frequencies and rather may be involved in predator avoidance (see above). Pattern recognition and directional information appear to be processed in a serial manner in the brain (Schul, J. *et al.*, 1998; Section 3.31.3.22). Behavioral experiments provide evidence for resonant neural networks underlying pulse-rate recognition in *T. cantans* (Bush, S. L. and Schul, J., 2006). Female phonotaxis is activated by the pulse rate of the species-specific song and by subharmonics of it. This type of response selectivity is expected if acoustically driven activity interacts with a neural network that oscillates at the species-typical rate (see also Hennig, R.M. *et al.*, 2004).

A fundamentally different method of pattern recognition underlies acoustic communication in duetting phaneropterine tettigoniids. Males and females communicate with sequences of short high-frequency sound pulses (Spooner, J. D., 1968; Hartley, J. C. and Robinson, D. J., 1976; Robinson, D. J. *et al.*, 1986; Heller, K.-G. and von Helversen, O., 1986; von Helversen, O. *et al.*, 2001; Stumpner, A. and Meyer, S., 2001). Males generate a chirp, that is, a series of sound pulses, which in some species are terminated with a final trigger pulse. When listening to the first series of sound pulses of a singing male the stationary females open their wings, in preparation for producing a response. The response occurs after the male's (trigger) pulses. By closing their wings females generate one to three high-frequency clicks less than 1 ms in duration. The time delay of the response is fixed and species-specific. In *Leptophyes* the response latency is just 28 ms (Zimmermann, U. *et al.*, 1989) and seems to constitute a thoracic acoustic motor reflex (Robinson, D. J. *et al.*, 1986), which is armed once the females have recognized the species-specific sequence of male sound pulses. Female sound pulses are extremely similar in different species (Stumpner, A. and Meyer, S., 2001) but males approach a conspecific female only if they perceive its response within a certain sensitive time window after their own song (Heller, K.-G. and

von Helversen, D., 1986; Dobler, S. *et al.*, 1994). At the neural level, males must have a temporarily sensitized network that expects the female response and initiates phonotactic steering. Interneurons of tettigoniids have been described with respect to frequency processing (Stumpner, A., 1997; 1999; 2002), however the neural basis of this temporal filter is not known.

Some species of tettigoniids sing in choruses, with calls of individuals generated either in synchrony or alteration (Sismondo, E., 1990; Greenfield, M. D. and Roizen, I., 1993). The synchrony of signaling is not perfect and one male will lead its neighbors. When females are exposed to identical calls presented in close succession they prefer the leading signals (Greenfield, M. D. and Roizen, I., 1993; Snedden, W. A. and Greenfield, M. D., 1998). This is not due to physical masking of the following signal but rather to a neuronal precedence effect (Wallach, H. *et al.*, 1949; Wyttenbach, R. A. and Hoy, R. R., 1993) in which the first of two temporally and spatially separated signals reaching the CNS inhibits the response to the second signal. When two identical chirps separated in space (180°) and time (e.g., 120 ms) are presented to the tettigoniid *Mecopoda elongata,* simultaneous recordings from both thoracic local ON1 neurons demonstrate that the leading signal inhibits the response to the follower signal in the contralateral neuron. This inhibition is due to the reciprocal inhibition between ON1 neurons, an arrangement that functions to enhance the bilateral auditory contrast in directional processing, but in this system also contributes to the female preference for the calls of leading animals (Römer, H. *et al.*, 2002).

3.31.3.15 Selective Attention: Detecting the Loudest Singer

Complex acoustic situations are generated when several animals sing at the same time. Phonotaxis of a receiver then may be dominated by sound intensity (Greenfield, M.D. and Shelly, T. E., 1990) since intensity indicates the loudest/fittest singer or a nearby male that can be approached with the lowest risk of predation. Of course a loud signal will activate auditory afferents more strongly than simultaneously perceived softer signals. However, in crickets (Pollack, G. S., 1988; Poulet, J. F. A. and Hedwig, B., 2003b) and tettigoniids (Römer, H., 1993; Römer, H. and Krusch, M., 2000) additionally a cellular mechanism decreases and even suppresses the response to the quieter sound in central neurons. In local (ON1, cricket and tettigoniid) and in ascending thoracic auditory interneurons (AN1 cricket, AN2, tettigoniids) repetitive acoustic stimulation with the species-specific song elicits an excitatory response to each sound pulse. At the same time excitation leads to a slow hyperpolarization, caused by a fast increase in cytosolic Ca^{2+} that probably triggers a Ca^{2+}-activated K^{+} current (Sobel, E.C. and Tank, D. W., 1994. Baden, T. and Hedwig, B., 2007). Ca^{2+}-activated potassium currents depend on the level of cytosolic calcium and thereby indirectly on stimulus intensity. This has a significant consequence for the activity of the auditory neurons. When loud and soft sound pulses are presented simultaneously to a cricket (80/60 dB) or tettigoniid (60/45 dB), only the loud pulses that cause a strong depolarization overcome the inhibition and consequently govern the spike activity of the auditory neuron. The excitatory response to the softer sound pulses is shunted and these are not represented in the spike pattern (Pollack, G. S., 1988; Sobel, E. C. and Tank, D. W., 1994; Römer, H. and Krusch, M., 2000). This cellular mechanism, based on the coupling of inhibitory membrane conductances to excitation, acts like an automatic gain control. It adjusts the output of these auditory neurons depending on the input and drastically decreases the response to background noise. In tettigoniids it is effective at intensity differences of only 2–5 dB (Römer, H. and Krusch, M. 2000). Humans can switch their process of recognition to either ear at will (thereby solving the cocktail party problem (Cherry, E. C., 1953)). The mechanism described here for insects does not entail a volitional shift in attention, but combined with the directional sensitivity of the ears it allows the loudest signal to dominate perception at each side. Consequently side-specific different temporal patterns ascend to the brain for pattern recognition (Pollack, G. S., 1986; Figure 10).

3.31.3.16 Flies

Some members of two groups of parasitic flies (*Sarcophagidae/Emblemasoma* and *Tachinidae/Ormiini*) use acoustic cues to approach singing crickets and tettigoniids. Female flies locate the singing males of host species and deposit their larvae on them (Cade, W. H., 1975; Walker, T. J., 1993; Allen, G. R., 1995). Frequency sensitivity of the flies' ears is adapted to the host's communication signals. This allows peripheral filtering of an essential feature for host recognition (Robert, D. *et al.*, 1992; Lakes-Harlan, R. and Heller, K.-G., 1992). Convergent song preferences are shared between female crickets, *G. lineaticeps* (38 pulses s^{-1} 0.8–4.6 chirps s^{-1}) and the fly *O. ochracea* in Californian populations. Both crickets and flies prefer male calling songs with

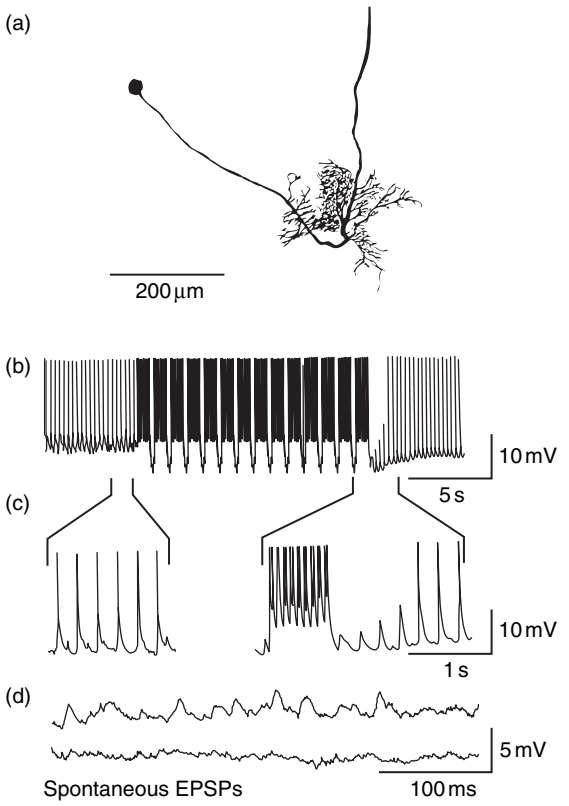

Figure 10 Suppression of background noise in tettigoniids. (a) Branching pattern of the ascending interneuron AN2 in the prothoracic ganglion of *Tettigonia viridissima*. Dendritic arborisations are located in the auditory neuropil, the axon ascends to the brain, and the soma is positioned to the left. (b) Intracellular recording of AN2. The neuron is stimulated via two ipsilateral speakers with a continuous sequence of pure tone bursts at a rate of 5 Hz (20 kHz, 50 dB SPL) and additionally with a conspecific song at 55 dB SPL. Note the hyperpolarization and the reduction in the EPSP amplitude at the end of the stimulation with the song pattern. Same data given in (c) with higher temporal resolution. (d) shows the amplitude of spontaneous EPSPs before and immediately after prolonged stimulation with the conspecific signal. (a) From Römer, H., Marquardt, V., and Hardt, M. 1988. Organisation of a sensory neuropile in the auditory pathway of two groups of Orthoptera. J. Comp. Neurol. 275, 201–215. (b–d) From Römer, H. and Krusch, M. 2000. A gain-control mechanism for processing of chorus sounds in the afferent auditory pathway of the bushcricket *Tettigonia viridissima* (Orthoptera; Tettigoniidae). J. Comp. Physiol. A 186, 181–191.

relatively high chirp rates and long chirp durations (Wagner, W. E., 1995). In *Therobia leonidei*, which parasitize tettigoniids, three auditory interneurons with tonic and phasic response properties have been characterized. They ascend from the sensory neuropil in the thoracic ganglion complex and terminate in the brain (Stumpner, A. and Lakes-Harlan, R., 1996).

3.31.3.17 Directional Processing

The physical cues for sound localization are generated by the properties of sound. For a source that is not in the median plane, the distance sound travels to each ear differs in a direction-dependent manner, generating an interaural time difference. Diffraction, reflection, and absorption of sound by body parts interposed between the ears will generate an interaural intensity difference. Because insects are small, both sorts of difference are minute. However, as described in Section 3.31.1.1 and elsewhere in this volume (see Monaural Sound Localization Using Spectral Cues) insects have evolved a number of mechanical specializations that exploit these small differences (Michelsen, A. and Löhe, G., 1995), bringing them into the working range of neural circuitry. In this section we consider how localization cues are represented and processed further within the CNS.

Time-of-arrival differences, even after mechanical preprocessing, are only on the order of a few tens of microseconds. Although such small differences can be resolved by brain circuits of higher vertebrates, there is no evidence that the nervous systems of insects are capable of such fine temporal processing. However, the relationship between stimulus amplitude and response latency of receptor neurons (see above) may generate millisecond-level interaural latency differences (Mörchen, A. *et al.*, 1978). Thus there are several ways in which interaural difference in stimulus amplitude (after mechanical preprocessing) may be represented: as differences in response latency of receptor neurons, in firing rates, and in the numbers of receptors for which threshold has been reached. These differences provide the raw material with which central circuits can work.

3.31.3.18 What Is the Neural Code for Sound Direction?

Translation of the physical cues for sound direction into behavior by flies is discussed by Hoy, R.R. and Robert, D. (Chapter 21, Perspective). Here we examine the processing of directional information in Orthoptera, the other group in which this issue has received considerable attention.

As noted above, a binaural difference in stimulus amplitude will lead to bilateral differences in both response latency and response strength. For natural stimuli, these two measures co-vary with stimulus direction, and tests of their relative contributions to

sound localization require that they be uncoupled. Independent stimulation of the two ears is difficult to achieve in freely behaving insects. However, quasi-dichotic stimulation of grasshoppers (*Ch. biguttulus*) was achieved by presenting stimuli from separate free-field loudspeakers on the insect's left and right (von Helversen, D. and Rheinlaender, J., 1988). Male grasshoppers turned toward the leading side with 75% accuracy for a time difference as small as 0.4 ms; performance was nearly perfect for a difference of 1.5 ms. These values are well within the range of bilateral latency differences of receptor neurons (Mörchen, A. *et al.*, 1978). The possible role of interaural intensity difference was investigated by playing just suprathreshold stimuli simultaneously from the two sides and varying their relative intensities. Reliable turning toward the more intense signal occurred for differences as small as 1–2 dB, values within the range that would be produced by the acoustic mechanisms for directionality. Similar sensitivity to binaural intensity difference has been shown in a tettigoniid (Rheinlaender, J. *et. al.*, 2006).

The effectiveness of binaural intensity difference was also demonstrated in crickets, which performed open-loop phonotaxis while walking on a spherical treadmill (Hedwig, B. and Poulet, J. F. A., 2005). Again, a bilateral difference of 1–2 dB was sufficient to elicit reliable steering toward the more intense stimulus. Time difference is apparently less important for crickets, with a modest tendency to turn toward the earlier signal appearing only for differences of 4 ms or more.

Bilateral differences in response timing and strength have also been decoupled by exploiting the adaptation characteristics of receptor neurons. Adaptation to rapidly repeated stimulation is expressed both as a decrease in spike rate and as an increase in latency. The effect on spike rate is greater for higher intensities (and thus for receptors serving the ear ipsilateral to the sound source), but the effect on latency is intensity independent (Sippel, M. and Breckow, J., 1984; Givois, V. and Pollack, G. S., 2000). Thus, adaptation causes a decrease, and sometimes even a reversal in sign, of the bilateral difference in response strength, but little or no change in the bilateral latency difference.

When crickets were exposed to a stimulus that produced strong adaptation but that was not behaviorally attractive, and were subsequently stimulated with an attractive pulse train, interaural differences in response strength and in latency could be uncoupled, at least transiently; for the first several sound pulses of the attractive stimulus, response strength could be greater on one side (the side opposite the adapting signal), yet latency could be shorter on the other side. Thus, the two potential cues for sound location disagreed. Under these conditions, crickets (assayed while performing tethered flight) turned most frequently toward the side where response strength was greatest (Pollack, G. S., 2003). Thus, as also shown by Hedwig B. and Poulet J. F. A . (2005), in crickets the bilateral difference in response strength, rather than in latency, is the dominant cue for localization.

3.31.3.19 Enhancement of Interaural Differences Through Bilateral Interactions

Bilateral differences in activity at the level of receptor neurons are amplified centrally through contralateral inhibition. The best-studied example of contralateral inhibition is that provided by the Omega neurons of crickets and tettigoniids.

3.31.3.20 Contralateral Inhibition in Gryllids

Two omega-shaped neurons occur on each side of the prothoracic ganglion of crickets. Omega neuron 1 (ON1) is a large, local interneuron in the prothoracic ganglion of crickets (Casaday, G. B. and Hoy, R. R., 1977; Popov, A. V. *et al.*, 1978; Wohlers, D. W. and Huber, F., 1978). It is most sensitive to the fundamental frequency of calling song, but also responds robustly to higher (including ultrasonic) frequencies (Wohlers, D. W. and Huber, F., 1982; Atkins, G. and Pollack, G. S., 1986). It has extensive processes in the auditory neuropil on both sides of the ganglion. The branches on the soma-ipsilateral side are dendritic and mainly postsynaptic, whereas the soma-contralateral branches show axonal terminals and are mainly presynaptic (Watson, A. H. D. and Hardt, M., 1996). The neuron receives input from receptors of the soma-ipsilateral ear, and inhibits several neurons receiving input from the other ear, including the ascending neurons AN1 and AN2, and its contralateral homolog (Selverston, A. *et al.*, 1985; Horseman, G. and Huber, F., 1994a; Faulkes, Z. and Pollack, G. S., 2000, Figure 11). This contralateral inhibition enhances binaural contrast (Kleindienst, H.-U. *et al.*, 1981; Horseman, G. and Huber, F., 1994b; Marsat, G. and Pollack, G. S., 2005), presumably facilitating sound localization. ON2 is similar in morphology, except that it has a dendritic process that crosses the midline. Ultrastructural studies suggest that, as

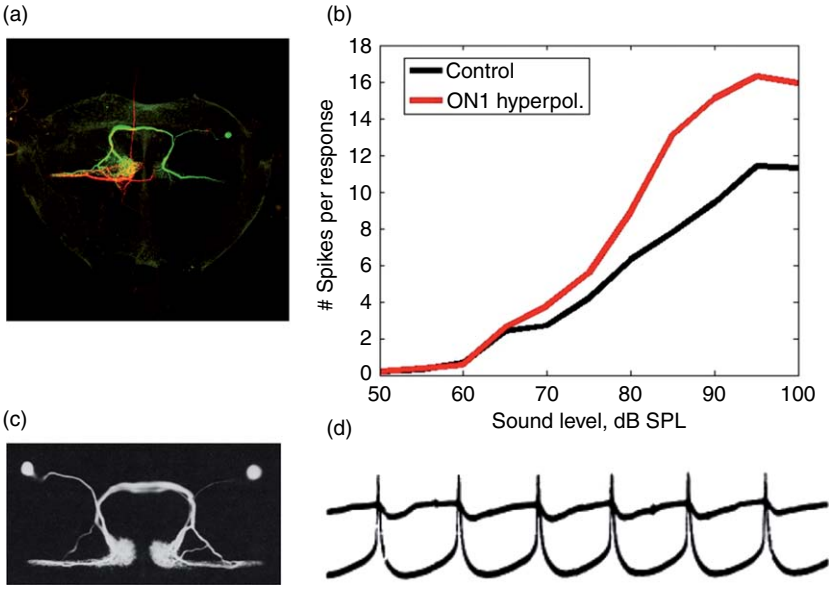

Figure 11 Contralateral inhibition in crickets. (a) The identified interneurons ON1 (green) and AN2 (red). Each neuron exists as a mirror–image pair. The AN2 shown receives auditory input from receptor neurons from the ear (not shown) to the left in this image; ON1 receives input from the ear to the right, and provides inhibitory input to AN2 (as well as to another identified neuron, AN1 – not shown – and to its contralateral homolog – see (c) and (d)). (b) Demonstration of contralateral inhibition. The curves show spike counts of AN2 responses to 30 kHz sound pulses, at various amplitudes, both without (black) and with (red) hyperpolarization of the contralateral ON1. When ON1 is hyperpolarized and its spikes suppressed, spike count of AN2 increases. (c) and (d) Mutual inhibition between the left and right ON1s. (c) Shows the anatomical relationships of the two neurons, both of which were stained here with intracellular dye injection. (d) Action potentials in one of the ON1s (bottom trace) are followed with short, constant latency, by IPSPs in the other ON1. (a) Pollack, G. S. (unpublished). (b) From Marsat, G. and Pollack, G. S., 2007. Efficient inhibition of bursts by bursts in the auditory system of crickets. J. Comp. Physiol. A 193, 625–633. (c, d) From Selverston, A. I, Kleindienst, H.-U., and Huber, F. 1985. Synaptic connectivity between cricket auditory interneurons as studied by selective photoinactivation. J. Neurosci. 5, 1283–1292.

for ON1, the soma-ipsilateral and soma-contralateral branches are mainly post- and presynaptic, respectively. However, unlike ON1, ON2 responds nearly equally well to stimuli from both sides (Wohlers, D. W. and Huber, F., 1982).

As noted above (see the section 'Frequency Analysis'), activity of the ascending neurons AN1 and AN2 influence the direction of phonotaxis; hyperpolarizing either of these neurons in crickets performing phonotaxis while walking results in directional errors away from the side of the silenced neuron. Horseman G. and Huber F. (1994b) the effect of contralateral inhibition in the network comprised of the left and right AN1s, AN2s, and ON1s. Contralateral inhibition received by ON1 and AN1 is relatively strong, whereas that of AN2 is weaker. Modeling the auditory pathway showed that contralateral inhibition strongly affects the bilateral difference in AN1s response, and more weakly affects that of AN2, in accordance with the relatively strong and weak effects of silencing these neurons on phonotaxis. The structure of this prothoracic network predicts that silencing ON1 should also affect phonotaxis accuracy. Hyperpolarization of ON1 in behaving animals resulted in a decrease in the tendency to turn toward the sound source, but only in three of eight animals tested (Schildberger, K. and Hörner, M., 1988). Killing ON1 (in another species) caused a tendency to circle toward the intact side. However, in this case the effects were seen only for stimuli with marginally acceptable temporal patterns; for an optimal stimulus pattern, killing ON1 had little effect on accuracy (Atkins, G. *et al.*, 1984).

A neuron probably homologous to ON1 of crickets also occurs in tettigoniids (Römer, H., 1987). As in crickets, ON1 of tettigoniids inhibits its contralateral partner. However, ablation experiments show that unlike ON1 of crickets, which accounts for all measurable contralateral inhibition (Faulkes, Z. and Pollack, G. S., 2000), this neuron is not the only source of contralateral inhibition in tettigoniids

(Molina, J. and Stumpner, A., 2005). Since there appears to be no ON2 in tettigoniids the additional source of contralateral inhibition is not yet known.

3.31.3.21 Contralateral Inhibition in Acridids

At least one local interneuron (BSN1) and two ascending neurons (AN1, AN2) of acridids are highly directional (Stumpner, A. and Ronacher, B., 1991); although micro-lesions in the connectives leading from the thorax to the brain point toward AN2 as the key neuron forwarding directional information to the brain and question the importance of AN1 (Ronacherl, B. *et al.*, 1993). The directionality of thoracic neurons is caused in part by contralateral inhibition (Suga, N., 1963). Direction-dependent inhibitory inputs are apparent as IPSPs in intracellular recordings of thoracic interneurons (Römer, H. *et al.*, 1981; Römer, H. and Dronse, R., 1982; Figure 12(a)),

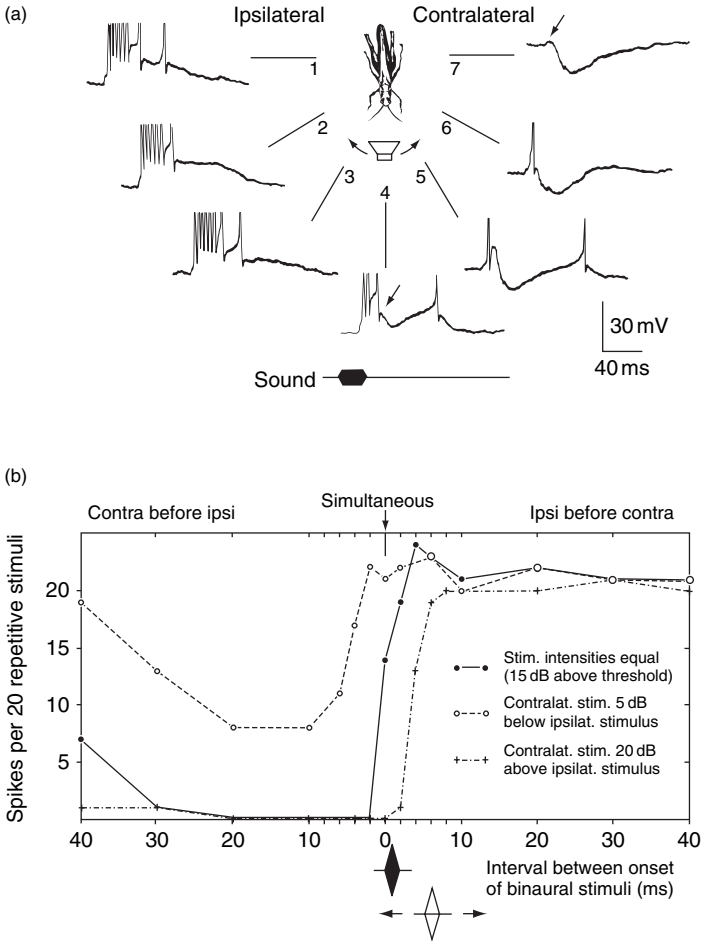

Figure 12 Directional processing in the locust auditory pathway. (a) Intracellular response of a directional sensitive interneuron in the metathoracic ganglion of the locust *Locusta migratoria*. Sound direction changed in steps of 30°. Excitatory responses are elicited upon ipsilateral stimulation (position 1) and pronounced IPSPs follow an initial excitation (arrow) when the stimulus is presented from contralateral (position 7). IPSPs occur at the transition of the speaker from ipsilateral to contralateral (arrow, position 4). Sound stimulus 20 ms, 20 kHz, 20 dB above ipsilateral threshold. (b) Effect of interaural time and intensity differences on the response of an auditory interneuron in the locust *Locusta migratoria*. Tympanic membranes were stimulated with contact-mechanical stimuli (69 kHz, 2 ms duration, repeated at 1 Hz). Excitation of the interneuron by ipsilateral stimulation (◆) and inhibition by contralateral stimulation (◇). The interval between binaural stimuli is systematically varied. The slope of the curves shifts by changing the difference in interaural stimulation intensities. (a) From Römer, H., Rheinlaender, J., and Dronse, R. 1981. Intracellular studies on auditory processing in the metathoracic ganglion of the locust. J. Comp. Physiol. A 144, 305–312. (b) From Rheinlaender, J. and Mörchen, A. 1979. 'Time-intensity trading' in locust auditory interneurons. Nature 281, 672–674.

but their source has not yet been identified. As for behavior (see above), responses of interneurons may be exquisitely sensitive to small difference in binaural timing and intensity (Rheinlaender, J. and Mörchen, A., 1979; Figure 12(b)).

3.31.3.22 Integration of Pattern Recognition and Sound Localization

3.31.3.22.1 Gryllids

Since crickets are selective for the more attractive pattern – when patterns are presented from different directions – it was proposed that inhibitory interaction between the two recognition systems might allow for discrimination of the better pattern (Pollack, G. S., 1986). Crickets steer to the side where the auditory pattern is represented best in the activity of ascending neurons. This led to the conclusion that pattern recognition and localization are organized serially, with the bilateral comparison that is the basis of localization being performed only after auditory information has passed through a recognition filter (Stabel, J. *et al.*, 1989, von Helversen, D. and von Helversen, O., 1995). However, rapid steering responses occur toward individual sound pulses in flying (Pollack, G. S. and Hoy, R. R., 1981) and walking (Hedwig, B. and Poulet, J. F. A., 2004; 2005) crickets. Rapid reflex-like steering is even elicited by the first pulses of chirps, when the animals had no chance to analyze the pulse rate of the perceived song. This demonstrates that orientation is not based on comparing the activity in both recognition systems. Moreover, orientation during phonotactic walking emerges from consecutive reactive steering responses to individual sound pulses. Even when an optimal pattern is presented from one side, the animals still respond toward nonattractive sound patterns presented on the other side (Hedwig, B. and Poulet, J. F. A., 2004). The reflex-like steering responses are under control of the brain and fail once the brain is disconnected from the CNS (Pollack, G. S. and Hoy, R. R., 1981).

3.31.3.22.2 Acridids

Directional information is functionally separated from pattern recognition at the metathoracic level, and ascends in a side-specific manner to the brain (Ronacher, B. *et al.*, 1986; von Helversen, D., 1997). The decision on turning direction appears to be made in the brain by a system comparing the directional information from both sides of the nerve cord (von Helversen, D. and von Helversen, O., 1990; 1995). When an efficient sound pattern is presented to one ear of a grasshopper and a nonefficient pattern with better directional cues to the other, the animals will turn not toward the attractive sound pattern, but rather toward the pattern with the better directional information. This indicates that the turning decision is independent of pattern recognition, however pattern recognition finally gates the turning response (von Helversen, D. and von Helversen, O., 1990; 1995).

3.31.4 Integrating Hearing with Other Activities

Insect hearing organs are adapted to respond to sounds of predators and conspecifics. Because of their design and sensitivity, however, they may also be affected by the animal's own motor activity. Furthermore, during sound production the ears are exposed to the animal's self-generated sound. Here we look at the impact of motor activity on sound processing and demonstrate that different insects adopted different strategies ranging from behavioral adaptations to neural attenuation of the auditory pathway to deal with this problem.

3.31.4.1 Ventilation and Flight

In grasshoppers and crickets the ears are closely related to the ventilatory system and they are not mechanically decoupled from the animal's body. Consequently, ventilation and other motor activities have a strong impact on hearing. Changes in the air pressure of the tracheal system cause inward and outward movements of the tympanic membrane in grasshoppers (Schwabe, J., 1906; Meyer, J. and Hedwig, B., 1995; Meyer, J. and Elsner, N., 1995) reaching 90–120 µm in *Locusta migratoria*. These slow movements of the tympanic membrane change its auditory response properties and modulate the afferent activity. Tympanic membrane oscillations are generally attenuated in the range of 2–10 kHz and enhanced above 10 kHz, leading to corresponding changes in auditory afferent responses (Meyer, J. and Elsner, N., 1995). Ventilation thus distorts the perception of conspecific communication signals. In the grasshopper *Ch. biguttulus*, which uses frequency components for sex

recognition (von Helversen, D. and von Helversen, O., 1997), the males stop breathing for some seconds after generating a calling song. This is the time during which a female response would be most likely to occur (Meyer, J. *et al.*, 1993).

In grasshoppers and locusts ventilatory movements and flight motor activity also activate the primary auditory afferents so that they discharge in the rhythm of the motor pattern (Hedwig, B., 1988; 1989). In crickets the activity of auditory interneurons may be coupled to ventilation (Stout, J. F. and Huber, F., 1972) and during walking auditory afferents are activated by the front leg movements (Schildberger, K. *et al.*, 1988). Thus during motor activity auditory afferents and interneurons convey auditory responses and nonauditory noise and furthermore auditory activity may be transiently suppressed. This decreases the reliability of auditory information that is available for pattern recognition and orientation within the CNS.

3.31.4.2 Sound Production

A particular challenge for auditory processing occurs during acoustic communication since the auditory system of the singing animal is also exposed to any self-generated sounds. This may desensitize the sender's auditory pathway and self-generated and external sound may be mixed and muddled. Different strategies are used to deal with this problem.

3.31.4.2.1 Cicadas

In male cicadas the tympanal membranes of the ears and the sound producing tymbals are both backed by a large abdominal air chamber (Pringle, J. W. S., 1954; Hennig, R. M. *et al.*, 1994). Since the animals generate high-intensity sound patterns in the vicinity of their hearing organs (Young, D., 1990) the auditory organ is prone to overloading by self-generated sound. During singing, however, the detensor tympani and ventral longitudinal muscles contract and act on the tympanal rim so that the tympana relax and fold (Pringle, J. W. S., 1954; Hennig, R. M. *et al.*, 1994). Folding of the tympana reduces their tension and the sensitivity of the ears by 20 dB; however, it does not completely disable sound perception.

3.31.4.2.2 Grasshoppers

During singing acridid grasshoppers use the hind legs to scratch a row of cuticular pegs against the wings and produce broad frequency songs of 60–70 dB SPL. The tympanic membranes, which are positioned just beneath the wings, oscillate in phase with the self-generated sound and also move in phase with the stridulatory hind leg movements (Hedwig, B. and Meyer, J., 1994). Even in silently singing males – with wings removed – the contractions of the thoracic singing muscles cause tympanic membrane vibrations. The self-generated sounds and the mechanical vibrations of the thorax activate auditory afferents leading to depolarization and spiking of auditory interneurons during singing (Hedwig, B., 1986; 1990). Due to the limited dynamic range of the afferents their response to external sound stimuli is strongly masked and reduced. When sound stimuli occur in phase with self-generated sounds extracellular recordings give the impression that auditory interneurons may be switched off (Wolf, H. and von Helversen, O., 1986). Intracellular recordings however demonstrate that the neurons are depolarized and that there is no indication of central inhibition acting on the auditory pathway (Hedwig, B., 1990). Short silent intervals, which occur in most songs, allow the animals to perceive external stimuli (Hedwig, B. and Meyer, J., 1994). The impact of self-generated sounds on auditory processing may be one reason for some species of grasshoppers to use alternating singing activity during intraspecific communication.

3.31.4.2.3 Crickets

Male crickets produce songs of over 100 dB SPL. At least some species are enduring singers and constantly expose their auditory system to the self-generated sounds. No attenuation occurs within the peripheral auditory system and the ears and afferents fully respond to the self-generated sound pulses (Poulet, J. F. A. and Hedwig, B., 2001). Processing of self-generated sounds is modulated within the first stage of auditory processing. A corollary discharge interneuron (Poulet, J. F. A. and Hedwig, B., 2002; 2006) is driven by the singing central pattern generator and spikes in phase with sound production. The interneuron projects into the prothoracic auditory neuropil and presynaptically inhibits the auditory afferent terminals and at the same time postsynaptically inhibits the local and ascending auditory interneurons ON1, AN1, and AN2 (Poulet, J. F. A. and Hedwig, B., 2003a; 2003b). Inhibiting sound processing in phase with the self-generated sounds prevents the auditory pathway from desensitization and maintains the animal's sensitivity to respond to external sounds (Poulet, J. F. A. and Hedwig, B., 2002; 2003a; Figure 13).

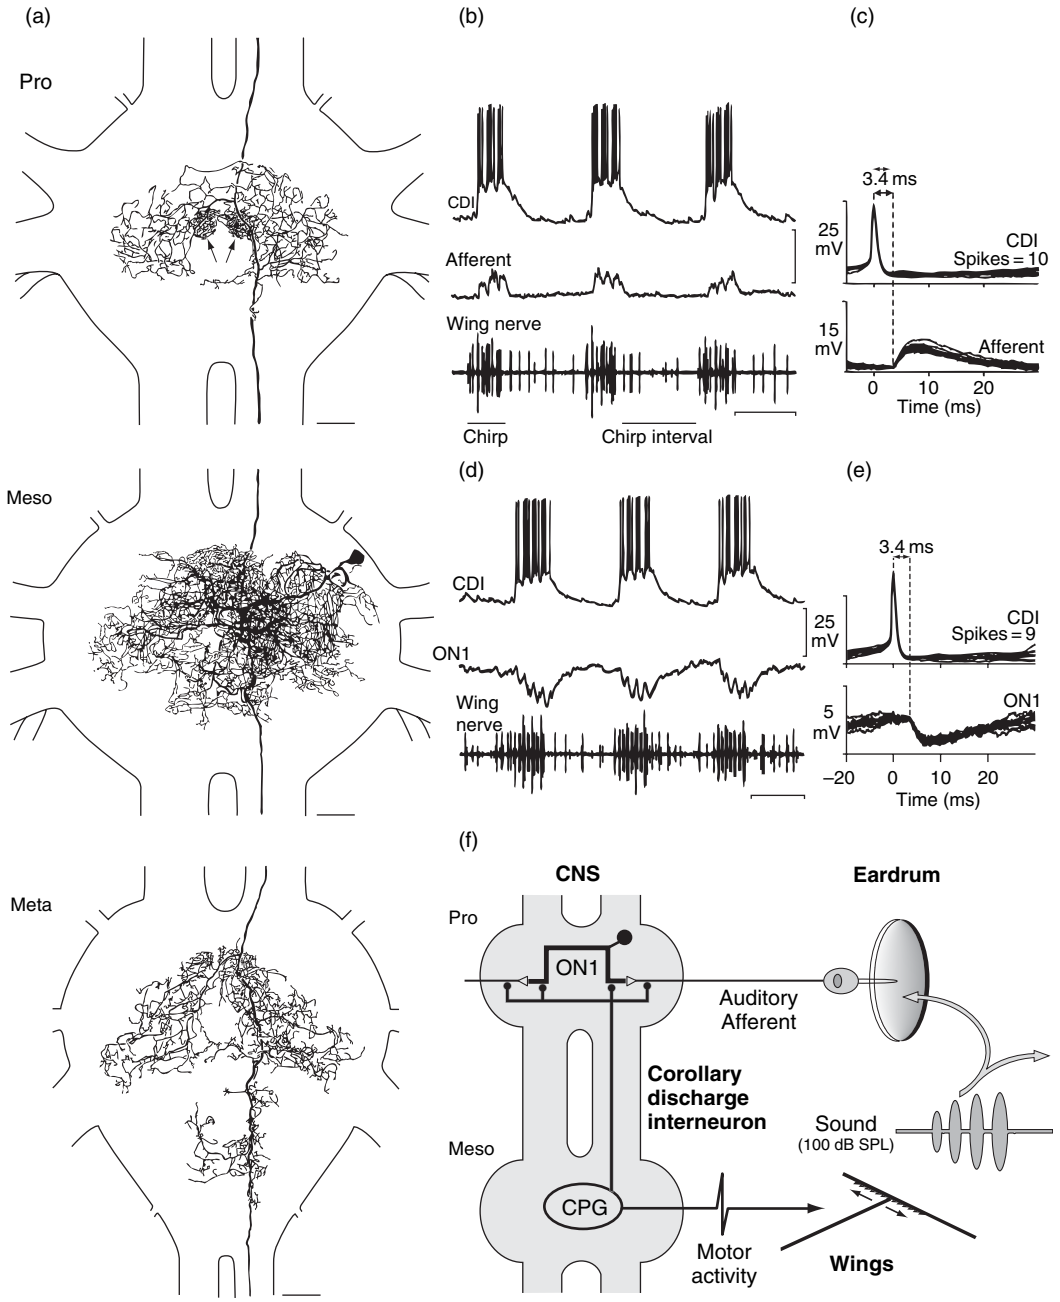

Figure 13 Corollary discharge interneuron controlling auditory processing in singing crickets. (a) Structure of the corollary discharge interneuron (CDI) in the CNS of a cricket that inhibits auditory neurons during stridulation. Extensive dendritic branches occur in the dorsal area of the mesothoracic ganglion and axonal branches in the prothoracic, the ventral area of the mesothoracic, and in the metathoracic ganglion. Axonal terminals are particular densely packed in the prothoracic auditory neuropil. The axons of the neuron extend to the brain and the terminal ganglion. The interneuron causes presynaptic inhibition of primary auditory afferents (b). Each spike in the neuron elicits a primary afferent depolarization in fictively singing crickets (c). The interneuron makes monosynaptic inhibitory connections to the ON1 neuron. Pronounced inhibition of ON1 occurs during the spike activity of CDI during singing (d). Each spike in CDI elicits an IPSP in the ON1 neuron (e). (f) During singing the ears of crickets are exposed to the self-generated sound. The CDI interneuron appears to be driven by the CPG for singing and pre- and postsynaptically inhibits the auditory pathway at afferent and interneuron level. (a–e) From Poulet, J. F. A. and Hedwig, B. 2006. The cellular basis of a corollary discharge. Science 311, 518–522. (f) From Hedwig, B. 2006. Pulses, patterns, paths: neurobiology of auditory behaviour in crickets. J. Comp. Glossary

action potential The action potential is a stereotyped electrical signal, consisting of a rapid, millisecond long, decrease in membrane potential, with a rapid return to the resting potential. Action potentials are typically 50–100 mV in amplitude. Action potentials serve to encode information as it is transmitted from one neuron to the next, and drive transmitter release from synapses.

anomalous rectifier Anomalous rectifier channels are those that are opened by hyperpolarization of the cell membrane as opposed to depolarization. They are anomalous because most channels are opened by depolarization.

brain slice The brain slice is a reduced preparation of the nervous system, in which a thin section of live brain tissue is obtained and maintained in an

artificial oxygenated balanced salt solution. Brain slices are typically between 0.25 and 0.5 mm thick. The slices have the advantages of mechanical stability and optical access, allowing careful biophysical analyses of individual cells and local neuronal circuits.

cation-selective channels Membrane proteins that are permeable to K, Na, and/or Ca are cation selective. Often this term is used for channels that do not have high selectivity, and so are permeable to more than one cation.

delayed rectifier Delayed rectifier is a term used to refer to the set of potassium conductances that repolarize the action potential. The term arises from the time-delayed activation of the membrane conductance, and because the membrane current–voltage relationship is nonlinear (nonohmic) when this conductance is active. Delayed rectifiers typically do not show significant inactivation.

depolarization Depolarization refers to movement of the membrane potential from its resting value, typically near −60 mV, toward more positive potentials, such as 0 mV. Depolarization of the neuronal membrane is often excitatory, in the sense that it increases the probability of triggering action potentials, or increasing the frequency of action potentials.

EPSC (excitatory postsynaptic current) EPSC refers to the current flow created when excitatory ligand-gated ion channels (such as glutamate and some acetylcholine receptors) are activated. The change in conductance, associated with a cation-selective channel, depolarizes the neuron and increases the probability of firing.

hyperpolarization Hyperpolarization refers to movement of the membrane potential from its resting value, typically near −60 mV, toward more negative potentials, such as −80 mV. Hyperpolarization of the neuronal membrane is often inhibitory, in the sense that it decreases the probability of triggering action potentials, or decreases the frequency of action potentials.

intrinsic firing pattern Intrinsic firing pattern refers to the temporal pattern of action potentials elicited by an extrinsic depolarization of the neuron membrane, in the absence of synaptic inputs. Typically, the pattern is defined with respect to simple rectangular current pulses injected into the cell.

node of Ranvier The node of Ranvier is a specialized region of the axon, where ion channels (sodium and potassium channels) are clustered. The nodes are located between the long stretches of the myelin sheath created by different myelinating glial cells (Schwann cells and oligodendrocytes).

pore loop The pore loop is the region of an ion channel protein that helps determine the selectivity of the channel, and plays a role in regulating the channel open or closed states. The pore loop often consists of a hairpin length of the protein inserted into the membrane, that begins and ends on the same side of the membrane.

tetrameric Tetrameric proteins have four subunits, often arising from the assembly of four distinct proteins encoded by different genes.

transient potassium current (or A current) The transient potassium currents are those that show inactivation, or an intrinsic closing, of the channels during a sustained change in membrane potential. This inactivation distinguishes these channels from delayed rectifiers. The time course of inactivation of transient potassium currents varies from about 10 ms to seconds, depending on the potassium channel subunits that make up the channel.

transmembrane domain Transmembrane domains are regions of a protein that are hydrophobic, so that they prefer to be inserted into the cell membrane such that the parts of the protein on either side of the domain are on opposite sides of the membrane.

3.32.1 Introduction

The auditory system faces unique challenges in processing the temporal and spectral features of sound, because sound contains biologically relevant information in timescales that are much faster than the capabilities of most common neuronal mechanisms. Most forebrain neurons have synaptic potentials that last tens of milliseconds and action potentials that are 2–5 ms wide. In comparison, the task of localizing sound in the azimuthal plane requires that the central auditory system compare spike trains with microsecond precision. Specializations of the standard neural processing mechanisms are thus necessary in the neurons and synapses of the auditory brainstem to meet these challenges (Oertel, D., 1999). Over the

past 15 years, these mechanisms have been identified and characterized in some detail. In particular, neurons in the auditory brainstem have phenotypes that result from the expression of specific patterns of ion channels and neurotransmitter receptors that produce temporal processing performance appropriate to the tasks of sound localization, sound identification, and sound perception for communication. In this chapter, the roles of voltage-gated potassium channels, which are highly expressed in auditory brainstem nuclei, and the role of cation-selective hyperpolarization-activated currents will be discussed. Equally important to the task of neural computation based on fine timing information are the synapses and their receptors; these too are specialized in the brainstem auditory system and are reviewed in 3.33.

We will begin by discussing the four primary firing pattern motifs that are found in brainstem auditory neurons. Next, we will briefly review the biophysics and structure of potassium channels, as these are the critical elements that endow auditory neurons with their ability to encode timing information. We will then review the expression of these channels along the auditory pathway in specific cell types. In the last section, we will discuss specific roles for these channels from the perspective of synaptic integration.

3.32.2 Firing Patterns

There are four fundamental motifs of electrical excitability that predominate in the brainstem auditory system (Figure 1). The first intrinsic pattern is a simple regular spiking pattern that is common to many neurons in the nervous system. In this case, a step depolarization of the cell membrane leads to a train of evenly spaced action potentials that can be sustained indefinitely (Figure 1(a)). The interval between the action potentials decreases as the injected current increases, and the rate does not change over time (in other words, there is no adaptation or slowing of firing as seen in many other neurons). The action potentials are narrow, and even in the best recordings reach only to about +10 mV (as compared to +40 mV for cortical neurons). The firing pattern is not sensitive to the membrane potential of the cell before depolarization (this will be important later). The cells in the ventral cochlear nucleus (VCN) that have this pattern are multipolar (or stellate) neurons (Wu, S. H. and Oertel, D., 1984) that receive many small bouton synapses from the auditory nerve fibers (ANFs). In response to sound *in vivo*, multipolar neurons fire trains of evenly spaced action potentials, similar to what is seen in brain slices with current injection. Cells with this firing pattern do not convey fine timing information necessary for speech perception or some types of sound localization, but may encode information about sound intensity or slower modulation of sound amplitude with their firing rate (Sullivan, W. E. and Konishi, M., 1984; Rhode, W. S. and Smith, P. H., 1986; Frisina, R. D. *et al.*, 1990; Kim, D. O. *et al.*, 1990).

The second intrinsic pattern is characterized by the presence of only one or two action potentials (Figure 1(b)) at the beginning of a depolarizing current step (Oertel, D., 1983). After these initial action potentials, the membrane potential stays close to the resting potential, and the membrane conductance is high. The action potentials may be wider than those in multipolar cells, and are often quite short. *In vivo*, neurons with these electrical properties may respond with patterns of action potentials that are similar to their inputs, or may respond only at the onset of a sound, depending on the strength and convergence of the inputs. Some neurons with these intrinsic properties can actually improve the temporal precision of firing relative to their inputs (Joris, P. X. *et al.*, 1994; Paolini, A. G. *et al.*, 2001; Louage, D. H. *et al.*, 2005). Neurons with this intrinsic pattern are commonly found in cells that process fine timing information, and the mechanisms underlying this processing will be discussed in more detail below.

The third intrinsic pattern is uniquely characterized by sensitivity of the cell's firing pattern to the membrane potential prior to a depolarization. Cells with this firing motif can fire a regular train of action potentials when the membrane potential has been at rest before current is injected (Figure 1(c), trace 1), but the timing of the first few spikes changes when the membrane potential is negative (hyperpolarized) to the resting potential before depolarization (Manis, P. B., 1990). Two different, related discharge patterns can occur. The first pattern has a first spike latency that is tens of milliseconds (Figure 1(c), trace 2), and the second pattern has a short first spike latency (Figure 1(c), trace 3), but long first interspike interval. The firing of subsequent spikes in these cells in response to depolarization is regular, and does not show adaptation, similar to the regular firing cells discussed above. A surprising feature is that these patterns closely resemble the patterns reported for

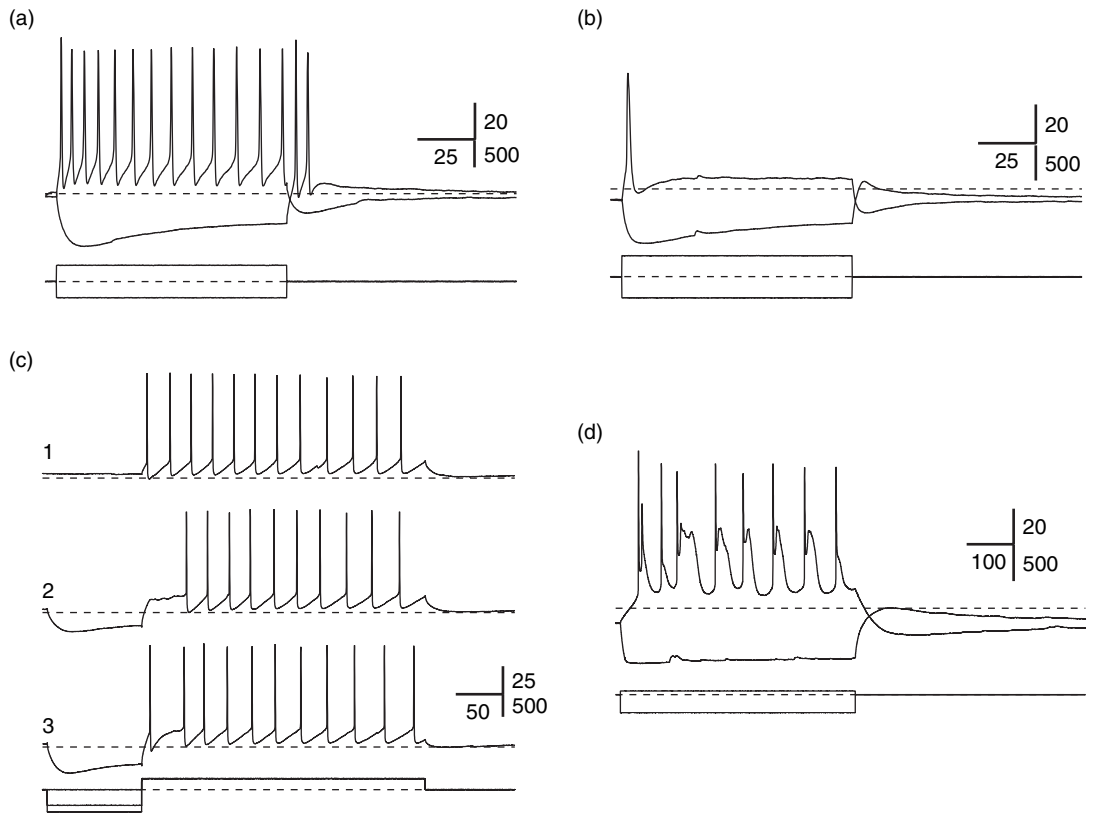

Figure 1 Example recording from cells in the cochlear nucleus with different intrinsic firing patterns. (a) Regular firing pattern (type I) found in stellate–multiploar cells of the ventral cochlear nucleus. Note occasional anodal break spikes following a hyperpolarizing current injection. Data from P23 mouse (DBA) ventral cochlear nucleus. (b) Phasic firing pattern (type II) found in bushy cells (including spherical and globular bushy cells); a slightly modified version of this pattern is found in octopus cells. Data from P35 mouse (DBA) ventral cochlear nucleus. (c) Three different voltage-dependent discharge patterns of dorsal cochlear nucleus (DCN) pyramidal cells. Trace 1 shows the regular firing elicited when the membrane potential is at rest. Trace 2 shows the delay to the first spike following a hyperpolarization. Trace 3 shows the slightly longer first interspike interval that is seen with larger hyperpolarizations, or with different hyperpolarization–depolarization sequences. Data from P13 rat DCN pyramidal cell. (d) Complex spiking pattern seen in cartwheel cells of the DCN. Note the related complex bursts and broad after depolarization when only single spikes are generated. Data from P12 rat DCN cartwheel cell. Calibrations: horizontal bars indicate time in milliseconds. Upward vertical bars are voltage in millivolts. Downward vertical bars indicate current, in picoamperes. For voltage traces the dashed lines are at −60 mV, except in (d), where they are at −75 mV. For current traces, the dashed lines are at 0 pA. Recordings in (a) and (b) from Wang Y. and Manis P. B. (unpublished data). Recording in (c) from Manis P. B. (unpublished data) Recording in (d) from Mancilla J. and Manis P. B. (unpublished data)

the responses to tone bursts for these cells *in vivo*. While these cells are not normally thought of as being involved in precise timing circuits, their intrinsic mechanisms are capable of encoding timing information (Manis, P. B. *et al.*, 2003; Kanold, P. O. and Manis, P. B., 2005) and so they are briefly discussed below.

The fourth motif is a bursting or complex spiking pattern, in which groups of action potentials occur closely together in time, with much longer intervals between the bursts (Figure 1(d)). This pattern is seen in cartwheel cells of the dorsal cochlear nucleus (DCN) (Zhang, S. and Oertel, D., 1993; Manis, P. B. *et al.*, 1994). Because these cells do not seem to be involved in timing circuits *per se*, and little is known about their channels, they will not be discussed further.

Each of these patterns is generated by neurons that express different complements, densities and possibly distributions of ion channels in their membrane. While the discharge patterns result from the interplay between the membrane voltage and all of the time and voltage dependences of the ion conductances, the potassium conductances vary most between the cells with different patterns. Therefore, we will focus on the potassium channels in this chapter.

3.32.3 Voltage-Gated Potassium Channels

Phylogenetically, the voltage-gated potassium channels are ancient, and homologous channels can be found in plants (Cherel, I., 2004). Even the ionotropic glutamate receptors have a pore domain that closely resembles an inverted pore from the voltage-gated potassium channels (Wo, Z. G. and Oswald, R. E., 1995; McFeeters, R. L. and Oswald, R. E., 2004). In mammals, voltage-gated potassium channels arise from several gene families with different properties (reviewed in Coetzee, W. A. *et al.*, 1999). The major known families include the Kv series, which are principally gated by membrane voltage, the KCNQ family (Robbins, J., 2001), some of which form the G-protein-gated channels associated with muscarinic receptors, the ether-a-go-go (ERG) channels that play a role in cardiac action potential repolarization (Schwarz, J. R. and Bauer, C. K., 2004), two calcium-dependent families (Sah, P. and Faber, E. S., 2002; Stocker, M., 2004), and a host of smaller two pore channels (O'Connell, A. D. *et al.*, 2002). In addition, cellular excitability is regulated by hyperpolarization-activated currents (HCN) (Robinson, R. B. and Siegelbaum, S. A., 2003). Each of these sets of channels performs different functions in regulating the excitability of neurons, and each exhibits a selective pattern of cellular expression in the nervous system. This review will focus on the Kv family; however, the HCN currents will also be discussed. Indeed, the principal regulation of electrical excitability in the brain seems to depend on the Kv, HCN, and K(Ca) currents, which together form the major voltage-dependent K^+ conductances in the cell membrane. The next best-studied group of channels, the calcium-activated potassium channels, are also important in some auditory neurons for regulating spike frequency and firing rate accommodation.

For the other classes of channels, much less is known about their distribution in the central auditory system or their contribution to electrical excitability. In particular, KCNQ4 channels have a very interesting pattern of expression in brainstem auditory nuclei, being prominent in the anterior ventral cochlear nucleus (AVCN), and ventral nucleus of the lateral lemniscus (Kharkovets, T. *et al.*, 2000). The pattern of expression is limited to just a few brainstem nuclei (not all of which are auditory). So far, no currents attributable to these channels have been identified. Two other sets of channels are also known to be expressed at high levels in some neurons of the auditory brainstem. Two-pore potassium channels are found throughout the nervous system, and some show high levels of expression in specific auditory brainstem nuclei (Karschin, C. *et al.*, 2001; Pal, B. *et al.*, 2005; Chen, W. C. and Davis, R. L., 2006; Holt, A. G. *et al.*, 2006). The TASK-5 channel is specifically highly expressed in cochlear nucleus and some nuclei of the superior olivary complex, but is notably not expressed in the medial nucleus of trapezoid body (MNTB) (Karschin, C. *et al.*, 2001). Potassium-dependent sodium channels, Slick and Slack (Bhattacharjee, A. and Kaczmarek, L. K., 2005) are also found widely, but have a particular pattern of expression in the auditory system. Slack has been localized to the calyces of Held in the MNTB (Bhattacharjee, A. *et al.*, 2002), while Slick is found in the VCN, lateral superior olive (LSO), and MNTB (Bhattacharjee, A. *et al.*, 2005). It is likely that these channels play an important role in regulating repetitive firing. While these and other channels are likely very important for some aspects of neural processing, and in setting the membrane potential, they are in need of further experimental analysis. This requires pharmacological and genetic tools that allow specific analysis of their contribution to the physiological functions of neurons.

3.32.3.1 The Kv Family

Voltage-gated potassium channels consist of tetrameric assemblies of proteins with six transmembrane domains, with a pore loop located between the fifth and sixth transmembrane spans. The specific assembly of the channel subunits is thought to be governed by C-terminal protein interactions such that all of the subunits of a given channel must belong to a single family. Thus, while there are specific rules regarding assembly, the number of different combinations of channel assemblies that can be produced is potentially quite large.

Several Kv genes are known to have splice variants (Kv1.5, Kv3.1, Kv3.2, Kv3.3, Kv3.4, and Kv4.3). However, there is no evidence for posttranslational editing of these channels in mammals. At least for Kv1, glycosylation can alter channel function (Thornhill, W. *et al.*, 1996). In addition, the biophysical behavior of the channels can vary considerably, even within a family, giving a wide range of potential channel function according to the rules of assembly. The details of channel assembly are not well understood, but are known to depend on both targeting motifs in the

protein that regulate channel trafficking to the membrane, and specific interactions among subunits at the level of the endoplasmic reticulum (Heusser, K. and Schwappach, B., 2005). In addition, auxiliary subunits (β subunits) have been shown to act as chaperones, and influence the targeting and assembly of the channels, as well as gating in assembled channels.

Ultimately, the pore-conducting portion of the Kv channels (referred to as the α subunits) are associated with β subunits in a 1:1 α–β stoichiometry. The β subunits play an important modulatory role in channel function, sometimes in conjunction with channel interacting proteins. Furthermore, the localization of Kv channels can be regulated by motifs that can target the channels to postsynaptic densities. Channel localization in the membrane is not random, but is, at least for some channels, quite focal. For example, Kv4.2 has been found to be targeted to postsynaptic densities in preoptic neurons (Alonso, G. and Widmer, H., 1997). This allows the channels to interact with other proteins, and may also facilitate local modulation by short-range messengers.

Because specific families of Kv channels have particular properties, it is useful to briefly review the families and the properties of the channels as expressed as homomers in heterologous systems. Such a description is useful in considering the potential functional contribution of the channels in auditory neurons.

3.32.3.1.1 The Kv1 family

The Kv1 family of channels is homologous to the Drosophila *shaker* family. There are currently seven genes that are known to be associated with this family, and their functional conductance and kinetics in heterologous expression systems is somewhat diverse. All of these have been detected in at least some regions of the brain, although Kv1.7 is not highly expressed (Kalman, K. *et al.*, 1998). Kv1.1 and Kv1.2 channels are found principally in axons, terminals (such as cerebellar basket cells) and cell somata, although Kv1.2 can also be found in dendrites (Sheng, M. *et al.*, 1994). In the axon, they are localized in a juxtaparanodal position (Rasband, M. N. and Trimmer, J. S., 2001; Rasband, M. N., 2004). These channels play the role of a delayed rectifier, where they repolarize the axonal action potential. Kv1.1 and Kv1.2 are also highly expressed in the auditory brainstem, as will be discussed in detail below. Kv1.4 channels are also found principally in axons and axon terminals (Sheng, M. *et al.*, 1992), and form an inactivating current that is sensitive to tetraethylammonium (TEA) and 4-aminopyridine (4-AP) (however, a unique localization has been reported in the auditory system, as discussed below). Kv1.4 gating is strongly accelerated by β subunit association (Castellino, R. C. *et al.*, 1995). While Kv1.4 contributes to some A currents (inactivating or transient potassium currents) in brain, other channels, such as Kv3.4, Kv4.2, and Kv4.3 can also be responsible for these currents (see below). Simply taking into account the seven members of the Kv1 α family and their tetrameric assembly, and ignoring issues related to β subunits or other proteins, or assembly order (adjacency), it is obvious that there exists the potential for a large number of different subunit combinations. In practice, however, any given cell seems to express only a subset of the family, and so the potential heteromultimeric composition of membrane channels is far more limited. In brain, immunoprecipitation experiments have shown that heteromeric combinations of Kv1.1–Kv1.2, Kv1.1–Kv1.4, Kv1.1–Kv1.2–Kv1.6, and homomeric Kv1.2 predominate (Wang, H. *et al.*, 1999).

3.32.3.1.2 The Kv2 family

The Kv2 family of channels is homologous to the Drosophila *shab* family. There are two known members of this family, and both are widely expressed in brain. Kv2 channels are high-voltage-activated, TEA- and 4-AP-sensitive delayed rectifiers (Shi, G. *et al.*, 1994). Kv2 channels have not been extensively studied in the auditory system, although they are reported to be expressed in the cochlear nucleus (Fitzakerley, J. L. and Quale, M., 2005) and inferior colliculus (Hwang, P. M. *et al.*, 1993; Richardson, F. C. and Kaczmarek, L. K., 2000).

3.32.3.1.3 The Kv3 family

The Kv3 family of channels is homologous to the Drosophila *shaw* family. There are four known members of the family, and one member, Kv3.1 can exist as one of two splice variants, known as Kv3.1*a* and and Kv3.1*b* (Luneau, C. J. *et al.*, 1991). While Kv3.1 is especially found in the forebrain in gamma-aminobutyric acid (GABA)ergic interneurons, it is highly expressed in auditory brainstem neurons that are both glutamergic and glycinergic (Perney, T. M. *et al.*, 1992; Perney, T. M. and Kaczmarek, L. K., 1997), and thus is of significant interest in auditory processing. Kv3.1 channels form high-threshold delayed rectifiers, with activation near −10 mV and incomplete slow inactivation. Kv3.2 channels are also delayed rectifiers, and are expressed in many cells, including in the auditory brainstem (Weiser, M. *et al.*,

1994). Kv3.3 and Kv3.4, in contrast, show a relatively deep, slow inactivation.

3.32.3.1.4 The Kv4 family

The Kv4 family of channels is homologous to the Drosophila *shal* family. There are three known members of the family, and one member, Kv4.3 can exist in multiple splice variants (Ohya, S. *et al.*, 1997). Kv4.1 is not expressed in the brain, but Kv4.2 and Kv4.3 are expressed in throughout the neural axis, but in specific populations of neurons (Serodio, P. and Rudy, B., 1998). Due to a particular targeting motif (Rivera, J. F. *et al.*, 2003), these channels are largely found in dendrites, and not in axons or synaptic terminals (Sheng, M. *et al.*, 1992). The channels are all rapidly and nearly completely inactivating, and their gating is subject to modulation by a number of factors, including arachidonic acid (Villarroel, A. and Schwartz, T. L., 1996) and phosphorylation by various kinases (Yuan, L. L. *et al.*, 2002; Varga, A. W. *et al.*, 2004). A particularly important set of regulatory proteins that interact with the Kv4 family of channels are the the KChip proteins (An, W. F. *et al.*, 2000). These proteins confer a calcium sensitivity, as well as modulate activation and inactivation voltage dependence and gating kinetics. A surprisingly linear relationship between Kv4 family mRNA (including Kv4.2, Kv4.3, and *shal*) and the rapidly inactivating transient potassium current has been demonstrated in several cell types (Baro, D. J. *et al.*, 1997; Tkatch, T. *et al.*, 2000; Liss, B. *et al.*, 2001).

3.32.3.1.5 Kv5–Kv9

These are all accessory proteins that do not, on their own, form ion channels, but which can associate with other Kv channels (Coetzee, W. A. *et al.*, 1999). Their roles are less well defined, and their presence in auditory neurons has not been extensively explored. Kv9.1, which is present in the inferior colliculus, has been shown to modify Kv2.1 gating, so that cells may be able to fire more rapidly or entrain better (Richardson, F. C. and Kaczmarek, L. K., 2000).

3.32.4 Channel Specialization and Biophysical Characterization of the Channels in the Vertebrate Auditory Cental Nervous System

Since the initial work of Oertel D. (1983) it has been evident that neurons in the auditory brainstem could be differentiated by their intrinsic firing responses to rectangular current pulses. For many cell types, the intrinsic firing responses can be shown to be related or to underlie the acoustically evoked spike patterns, although this is not always a trivial relationship. The intrinsic firing patterns are regulated by three principal features of cells. First, and often most important, is the cell-specific selection of specific ion channels complexes; for example, which sets of Kv α and β subunits, in conjunction with any auxillary proteins such as the KChips, are expressed. Second, the firing patterns depend on the location and density of the channel proteins, which is a function of channel targeting. Finally, and to a lesser extent, the shape of the dendritic tree affects the patterns of current flow through the cell (Mainen, Z. F. and Sejnowski, T. J., 1996), so dendritic structure also influences the cell voltage at the spike initiation site, which is usually in the initial segment (Colbert, C. M. and Johnston, D., 1996; Stuart, G. *et al.*, 1997; Colbert, C. M. and Pan, E., 2002).

In this section, we will review the patterns of ion channel expression in a number of nuclei and cell types of the auditory brainstem. There are a number of caveats on the interpretation of data in the literature that should be recognized before we delve into this section. The first is that expression of channels in a single cell population can show differences among species; a prime example of this is in heart, where atrial I_{to} (the transient outward current) is mediated by Kv4.2 channels in rat (Bou-Abboud, E. and Nerbonne, J. M., 1999), but is mediated by heteromultimers of Kv4.2 and Kv4.3 channels in mice (Guo, W. *et al.*, 2002). While the intrinsic physiology of most auditory neurons seems comparable across species, the underlying channel composition may vary. Second, channel expression is regulated during development, sometimes in a nonmonotonic manner, and is not complete (in rodents) until late adolescence (e.g., ~30 days of age in rats and mice). Thus, the ages of animals used for physiological analyses is an important variable. Third, the technical limitations of message and protein localization studies should always be carefully considered. The presence of a particular mRNA in a cell does reveal the cellular localization of the presumptive protein(s); in most cases the level of mRNA is also not necessarily correlated with the level of functional protein in the membrane (an exception is for Kv4.2, as discussed above). Proteins can be localized by immunocytochemistry, but the limits on the specificity of the available antibodies suggest some caution is warranted in interpreting these results, and localization of proteins in relevant membrane compartments can be difficult to demonstrate, particularly in the auditory brainstem where the nuclei often have

a complex neuropil, multiple fiber systems, and nonlaminar organization. Physiological studies directly demonstrate the existence of different kinds of channels in specific cell types, but require the use of pharmacological or genetic manipulations to identify specific types of channels, and frequently cannot assay protein function in dendritic or axonal processes.

3.32.4.1 Spiral Ganglion Cells

A recent discovery was the identification of a diversity of discharge characteristics in spiral ganglion cells (SGCs). SGCs are endowed with rapidly inactivating sodium channels, a low-voltage-activating potassium current, a transient potassium current, hyperpolarization-activated currents, and calcium channels (Yamaguchi, K. and Ohmori, H., 1990; Sheppard, D. N. *et al.*, 1992; Valverde, M. A. *et al.*, 1992; Santos-Sacchi, J., 1993; Garcia-Diaz, J. F., 1999; Adamson, C. L. *et al.*, 2002b; Mo, Z. L. *et al.*, 2002). Studies using cultured neurons showed that the transient current and the low-voltage-activating current could vary along the length of the modiolus (Adamson, C. L. *et al.*, 2002a; 2002b). In response to current pulses, high-frequency (cochlear base) cells showed shorter latency action potentials and phasic firing, and in older cultures, narrower action potentials, whereas low-frequency (cochlear apex) cells more frequently showed repetitive firing and longer latency action potentials to current pulses. These physiological features correlated with a higher expression (as assayed by a semiquantitive immunocytochemical method) of Kv1.1 and Kv3.1 in the base, whereas Kv4.2 was slightly more highly expressed in the apex. These results suggest that there may be differential processing of temporal information along the length of the cochlea. Given that the representation of the temporal structure of sound in SGCs varies with cochlear location (e.g., see Louage, D. H. *et al.*, 2004), perhaps this is not surprising. Nonetheless, the role of these channel configurations in temporal coding in the spiral ganglion cell (SGC) is still not well understood, although some clues may be derived from work in the central auditory system, as discussed next.

3.32.4.2 Ventral Cochear Nucleus Bushy Cells

3.32.4.2.1 The low voltage-activated potassium conductance

Since the pioneering studies of Oertel (Oertel, D., 1983; Wu, S. H. and Oertel, D., 1984) in mouse cochlear nucleus brain slices, it has been evident that bushy neurons have specialized electrical excitability. The principal signature of these cells when recorded in current clamp is a strong outward rectification that opposes depolarizing currents, and limits the cell membrane potential to not move too far above the resting potential (Figure 1(b)). This rectification was associated with a significant increase in membrane conductance. Initial voltage clamp studies from acutely isolated guinea-pig VCN neurons showed that the rectification could be explained by the presence of a strong, low-voltage-activated (often called low-threshold, or I_{LTK}) potassium conductance (Manis, P. and Marx, S., 1991) that was partially blocked by 4-AP, but was not blocked by TEA. The cardinal characteristics of this conductance are that it is partially activated at rest, it shows modest, voltage-dependent inactivation, and that activation from potentials near rest (−60 mV) has a monoexponential time course. Subsequently, depolarization from more negative potentials revealed a sigmoidal activation time course (Rothman, J. S. and Manis, P. B., 2003a), consistent with cooperative gating of four subunits during channel opening. Estimates of the maximal conductance in isolated cells revealed a mean value of about 200 nS for a 12 pF cell, but the conductance varied over a wide range. In addition, the voltage at which the conductance yielded a current of 0.1 nA also showed wide variability (Rothman, J. S. and Manis, P.B., 2003c), suggesting that the voltage dependence of activation, and therefore the availability of the conductance to participate in synaptic integration, is not constant among VCN cells.

In both rat and guinea-pig, I_{LTK} has been shown to be sensitive to the mamba snake toxin, dendrotoxin (DTX)-I (Dodson, P. D. *et al.*, 2003; Rothman, J. S. and Manis, P.B., 2003a; 2003c; Pal, B. *et al.*, 2004), which blocks Kv1.1- and Kv1.2-containing channels (Hopkins, W. F., 1998). The low-voltage-activated conductance has been reported to be blocked in a subset of bushy cells by tityustoxin-Kα, which blocks only Kv1.2-containing channels (Dodson, P. D. *et al.*, 2003), suggesting that either bushy cells are heterogeneous in their channel expression, or that not all cells express Kv1.2-containing channels within the spatial reach of the voltage clamp, for example, on or near the soma. A very similar conductance is present in neurons of the chicken nucleus magnocellularis that are homologous to the mammalian bushy cells (Reyes, A. D. *et al.*, 1994; Zhang, S. and Trussell, L. O., 1994; Rathouz, M. and Trussell, L., 1998;

Fukui, I. and Ohmori, H., 2003; 2004; Lu, Y. *et al.*, 2004). The similarities of the conductance extend to the voltage dependence, apparent density (as estimated from currents recorded in somatic voltage clamp), sensitivity to 4-AP and DTXs, and the presence of partial inactivation with prolonged steps.

The pharmacological profile of block by 4-AP and DTXs suggests that the low-voltage-activated conductance in bushy neurons is mediated by channel complexes containing both Kv1.1 and Kv1.2. Three additional lines of evidence support this conclusion. First, the mRNA for both channel subunits is widely expressed in mouse VCN (Grigg, J. J. *et al.*, 2000), although colocalization of multiple messages has not been attempted. In addition, while it is clear that the major populations of bushy and octopus neurons have the message (see below), it is less clear whether the multipolar cell classes express the message. Neither immunocytochemical nor *in situ* hybridization studies have attempted to positively identify cell types using classical criteria. Second, preliminary single-cell PCR studies (Sonnenburg, R. *et al.*, 2002) have shown coexpression of Kv1.1 and Kv1.2 message in individual bushy neurons in the rat VCN, but surprisingly, these channels were also found in a subset of regular firing (stellate) neurons, suggesting that their expression is not limited to cells expressing a low-voltage-activated conductance. Third, positive immunostaining for Kv1.1 and Kv1.2 is widely apparent in the VCN, including in the bushy cell populations (Dodson, P. D. *et al.*, 2003; Caminos, E. *et al.*, 2005; Pal, B. *et al.*, 2005; Bortone, D. S. *et al.*, 2006), as might be expected from their expression of DTX-sensitive low-voltage-activated K^+ currents. However, it remains unclear as to whether the channels are coexpressed in individual cells, and if they are, whether the functional channels are actually coassembled in the membrane. In addition, a recent report of immunostaining for Kv1.3 and Kv1.6 in the rat VCN (Pal, B. *et al.*, 2005) raises additional questions about the composition of channel complexes. Thus, while Kv1.1 and Kv1.2 seem likely to be key components of the conductance, the pharmacological data, together with immunocytochemical observations and the variations in the activation threshold of the potassium conductance (Rothman, J. S. and Manis, P. B., 2003c), also support the idea that there is heterogeneity across cells in the function and molecular composition of the low-voltage-activated current in the VCN.

Hallows J. L. and Tempel B. L. (1998) examined the developmental profile of Kv1.1 message in whole brain. The mRNA for Kv1.1 showed a spike during embryonic development, and did not increase again until between P12 and P15, with levels remaining stable after P15. Using real-time PCR, message in cochlear nucleus increases from P3 until P28 (Manis, P. *et al.*, 2002; Bortone, D. S. *et al.*, 2006). The reason for the later maturation compared to whole brain is not clear; however, the results suggest regional differences in the development of potassium channels. Mechanisms related to the control of expression of these channels are not well understood. Transcriptional control of Kv1 channels has only partially been elucidated (Wymore, R. S. *et al.*, 1996; Jang, G. M. *et al.*, 2004).

3.32.4.2.2 The high voltage-activated potassium conductance

In the initial studies of guinea-pig VCN neurons (Manis, P. and Marx, S., 1991), a second potassium conductance was characterized. This conductance activated at more positive voltages, and was blocked both by TEA and 4-AP. It also showed slower activation kinetics, and only a small amount of inactivation. A similar conductance, which is also insensitive to DTXs, but which can be blocked by low concentrations of 4-AP, has been seen in all subsequent studies in both mammals and avians (Reyes, A. D. *et al.*, 1994; Rathouz, M. and Trussell, L., 1998; Rothman, J. S. and Manis, P. B., 2003a; 2003c; Pal, B. *et al.*, 2004). This high-threshold conductance (I_{HT}) is not as strong as the low-voltage-activated conductance, activates slightly more slowly, and appears to have two kinetically distinct activation components (Rothman, J. S. and Manis, P.B., 2003a). There is also evidence for heterogeneity in deactivation time constants (Manis, P. *et al.*, 1996) suggesting that there may be multiple channels contributing to the conductance. This conductance is thought to be mediated by channels containing Kv3.1, as this subunit is highly expressed in the auditory brainstem, and particularly in bushy neurons of the cochlear nucleus (Perney, T. M. *et al.*, 1992; Perney, T. M. and Kaczmarek, L. K., 1997; Grigg, J. J. *et al.*, 2000). The properties and pharmacology of the conductance are generally consistent with those of heterologously expressed channels.

In whole brain (Perney, T. M. *et al.*, 1992), in the cochlear nucleus (Bortone, D. S. *et al.*, 2006), and in the inferior colliculus (Liu, S. J. and Kaczmarek, L. K., 1998a; Liu, S. Q and Kaczmarek, L. K., 1998b), Kv3.1 mRNA increases through development. Kv3.1 transcription is regulated by a cAMP response element (Gan, L. *et al.*, 1996), and indirectly by electrical

activity (Liu, S. J. and Kaczmarek, L. K., 1998a; Liu, S. Q and Kaczmarek, L. K., 1998b; von Hehn, C. A. *et al.*, 2004). In DBA2/J mice, which undergo an age-related high-frequency hearing loss (Zheng, Q. Y. *et al.*, 1999), the expression pattern of Kv3.1 is disrupted in high-frequency regions of the VCN, suggesting an activity-dependent regulation (von Hehn, C. A. *et al.*, 2004).

3.32.4.2.3 The transient potassium conductances

While rapidly inactivating potassium currents (I_A) are not a feature of bushy neurons in adult guinea-pig, even when conditions were optimized for their detection (Manis, P. and Marx, S., 1991; Rothman, J. S. and Manis, P. B., 2003a), they have been reported in embryonic chickens (Rathouz, M. and Trussell, L., 1998), and early postnatal rats and gerbils (Schwarz, D. W. and Puil, E., 1997; Pal, B. *et al.*, 2004). Consistent with their possible presence in bushy cells in rats and mice, Kv4.2 (but not Kv4.1 or Kv4.3) has been detected immunocytochemically in the VCN of P4-10 rats (Pal, B. *et al.*, 2005), and by *in situ* hybridization in the juvenile mouse cochlear nucleus (Fitzakerley, J. L. *et al.*, 2000). There are several possible explanations for the different expression patterns, including age or species differences.

3.32.4.2.4 The hyperpolarization-activated conductances

VCN bushy neurons have a strong hyperpolarization-activated conductance (I_H), which has been partially characterized (Rusznak, Z. *et al.*, 1996). This conductance is effectively blocked by cesium, but not barium, shows half-activation at −95 mV, and reverses at −33 mV. It is not prominent in isolated cells, presumably because the enzymatic treatment inactivates the channels. HCN1 and HCN2 are both strongly expressed by VCN bushy neurons (Koch, U. *et al.*, 2004). The specific roles of HCN channels in the VCN are not known, although it is likely that they contribute to setting the membrane potential and thereby regulating the level of activation of I_{LTK}. As such, they may be served as a transducer of modulatory influences, as suggested in the MNTB (Banks, M. I. and Smith, P. H., 1992).

3.32.4.3 Ventral Cochlear Nucleus Stellate/Multipolar Cells

Stellate neurons are not normally associated with the processing of high-frequency auditory events. They are characterized by having longer time constants as measured with small hyperpolarizing current pulses from rest, typically between 3 and 10 ms (White, J. A. *et al.*, 1994; Francis, H. W. and Manis, P. B., 2000), and regular firing (Figure 1(a)) upon depolarization (Oertel, D., 1983; Wu, S. H. and Oertel, D., 1984). Estimates of electrotonic structure suggest that these cells will significantly filter excitatory postsynaptic potentials (EPSPs) impinging on their dendrites (White, J. A. *et al.*, 1994). Voltage clamp studies show that stellate cells lack the low-voltage-activated conductance of bushy cells. However, they express a high-threshold K^+ current that is kinetically and pharmacologically indistinguishable from that in bushy neurons (Manis, P. and Marx, S., 1991; Rothman, J. S. and Manis, P.B., 2003a; 2003c).

Stellate cells can be distinguished along two different dimensions with respect to ion channel expression. The first is that the I_H currents show slower activation kinetics in T-stellate cells than in D-stellate cells (Fujino, K. and Oertel, D., 2001; Rodrigues, A. R. and Oertel, D., 2006). The second is that some cells (not classified as T- or D-stellate cells) exhibit a 4-AP-sensitive transient potassium current, whereas others do not (Manis, P. *et al.*, 1996; Rothman, J. S. and Manis, P. B., 2003c). The significance of these differences is not known.

3.32.4.4 Octopus Cells

Octopus cells are arguably one of the most interesting and perhaps extreme neurons in the cochlear nucleus. These cells have long dendrites that extend across the fascicles of ANFs in the posterior VCN, and so receive input from a broad region of the cochlea. In spite of this massive input, the cells fire only a single action potential at the beginning of tone bursts, with excellent precision (standard deviation 20–50 μs). They have also been reported to entrain, cycle by cycle, to tonal stimuli up to 1 kHz (Rhode, W. S. and Smith, P. H., 1986; Rhode, W. S. and Kettner, R. E., 1987). As such, they may also be among the most rapidly firing neurons in the brain.

Recordings from octopus cells show that they have very strong rectification around the resting potential, small action potentials at the soma (typically 10–20 mV), a low-input resistance of about 2.5 MΩ, and a short membrane time constant of 0.21 ms (Golding, N. L. *et al.*, 1999), which is close to the limit that can be measured with whole-cell recordings. These general properties arise from high levels of expression of both the low-voltage-activated

potassium current and I_H. I_{LTK} is similar to the current in bushy neurons. It is active at the resting potential, shows some inactivation over time in voltage clamp, and is variably blocked by DTX-I, DTX-K, α-DTX, δ-DTX, and tityustoxin (Bal, R. and Oertel, D., 2001). The selectivity of these toxins indicates that I_{LTK} in octopus cells includes Kv1.1, Kv1.2, and possibly Kv1.4 channels. The variability of block among cells by different toxins suggests that the pattern of channel expression varies among cells. The estimate of the total conductance in octopus cells is on the order of 500 nS, or roughly 2.5 times the conductance in bushy cells. While the low-voltage-activated current is so large that it is difficult to analyze across a wide voltage range under voltage clamp with patch pipettes, these estimates were obtained by partially blocking the current with α-DTX. However, it is quite possible that the conductance is even larger than this.

Octopus cells have DTX-resistant, TEA-sensitive current that activates at more positive voltages than the DTX-sensitive current (Bal, R. and Oertel, D., 2001). This I_{HT} is weak relative to the low-voltage-activated current, but is still substantial, with an estimated maximal conductance of about 115 nS (Bal, R. and Oertel, D., 2001). While there is a low level of Kv3.1 immunoreactivity in the octopus cell area (Perney, T. M. and Kaczmarek, L. K., 1997), Kv3.3 mRNA is clearly present in the octopus cells (Li, W. *et al.*, 2001) and could be the substrate for the I_{HT} current.

The I_H current in octopus cells has been more extensively characterized than in bushy cells (Bal, R. and Oertel, D., 2000), and it appears that I_H is much larger in these cells than any other cells in the brain. Similar to the current in bushy cells, it is blocked by extracellular cesium and ZD7288, but not by barium. The conductance is half-activated at −66 mV, and has a mixed cation (sodium and potassium) selectivity with a reversal potential of −38 mV. Perhaps most remarkable, the conductance is estimated to be 41% activated at rest, contributing about 62 nS of conductance to the cell membrane. Kinetics of activation showed two components at 44 and 180 ms, at −77 mV. This suggests a rapidly activating I_H. In terms of subunit composition, HCN1 is particularly clearly expressed in immunocytochemistry in octopus cells, whereas HCN2 is less clearly expressed in these cells, although it is found elsewhere (Koch, U. *et al.*, 2004). This conductance approximately balances the currents through the low-voltage-activated K channel at rest (Bal, R. and Oertel, D., 2001), so that subtle variations in voltage dependence or modulation by second messengers will affect the activation of the low-voltage-activated current (Cai, Y. *et al.*, 1997).

3.32.4.5 Dorsal Cochlear Nuclear Pyramidal Cells

DCN pyramidal cells can exhibit multiple discharge patterns in response to tones (Godfrey, D. A. *et al.*, 1975; Rhode, W. S. *et al.*, 1983) and in response to intracellular current steps (Manis, P. B., 1990). These discharge patterns (Figure 1(c)) are regulated by an interaction between transient potassium currents with different rates of inactivation (Kanold, P. O. and Manis, P. B., 1999) and subthreshold sodium conductances (Manis, P. B. *et al.*, 2003). One of the transient K^+ currents inactivates with a time constant between 11 and 20 ms, and shows a variable half-inactivation voltage. The other transient current inactivates with a time constant of about 200 ms, and activates at a more positive voltage. Following a hyperpolarization, depolarization activates the rapidly inactivating conductance, which can keep the membrane potential from reaching spike threshold. However, as this conductance inactivates, the membrane depolarizes. The depolarization is slowed by the slowly inactivating conductance, which continues to activate during the slow depolarization. The insensitivity of the rapidly inactivating current to 4-AP and TEA suggests that it is mediated by Kv4 family channels, of which Kv4.2 is most highly expressed in the DCN (Serodio, P. and Rudy, B., 1998; Fitzakerley, J. L. *et al.*, 2000). The slowly inactivating channel is sensitive to 4-AP and TEA, and may be mediated by a Kv3 or Kv1 family channel. A persistent (or slowly activating, relatively noninactivating) sodium current also provides the depolarizing drive necessary to produce long latency spikes in these cells. While pyramidal cells do not encode temporal information by phase locking, except at low frequencies, they may be able to encode a different kind of temporal information. Modeling based on the experimental measurements and range of kinetic parameters suggests that the relative timing of inhibitory and excitatory inputs can be reported by a small population of cells in which the half-inactivation (or magnitude) of the rapidly inactivating current varies (Kanold, P. O. and Manis, P. B., 2005). Thus, the cells may help analyze information about the relative timing of auditory and nonauditory events.

3.32.4.6 Superior Olivary Complex

3.32.4.6.1 Medial nucleus of trapezoid body

Neurons of the MNTB are often compared to VCN bushy cells, because they share several features, including a strong, multisite, afferent synapse (the calyx of Held), and they have firing properties and voltage-dependent conductances that resemble those of bushy cells (Banks, M. I. and Smith, P. H., 1992; Forsythe, I. D. and Barnes-Davies,M., 1993; Brew, H. M. and Forsythe, I. D., 1995). However, there are notable differences also. For example, MNTB neurons rarely fire more than one action potential when depolarized (Banks, M. I. and Smith, P. H., 1992; Forsythe, I. D. and Barnes-Davies, M., 1993), whereas VCN bushy neurons usually fire one, but up to three action potentials to a depolarizing current step. However, in mice at 22–25 °C, multiple action potentials have been reported (Brew, H. M. *et al.*, 2003). Second, the action potential height, as measured in brain slices at 33–34 °C, is slightly larger in MNTB neurons (~50 mV; Banks, M. I. and Smith, P. H., 1992) than in bushy neurons, where it averages 30–40 mV (Oertel, D., 1983; Francis, H. W. and Manis, P.B., 2000).

As with the VCN bushy cells, MNTB principal neurons possess a low-voltage-activated, potassium current and a high-threshold delayed rectifier. The low-voltage-activated current is reduced by 4-AP, and is blocked by DTX-I (Banks, M. I. and Smith, P. H., 1992; Forsythe, I. D. and Barnes-Davies, M., 1993; Brew, H. M. and Forsythe, I. D., 1995; Dodson, P. D. *et al.*, 2002). A detailed pharmacological dissection of the currents in rats (Dodson, P. D. *et al.*, 2002) showed that block by DTX-I is relatively complete, implicating Kv1 channels in the generation of the conductance. The current is also largely blocked by DTX-K, which is selective for Kv1.1-containing channels. Tityustoxin-Kα blocks about half of the low-voltage-activated current, suggesting that only a subpopulation of the channels contain Kv1.2. Noxiustoxin, which also blocks Kv1.2, as well as Kv1.3- and Kv 1.7-containing channels, also blocked about half of the current. Taken together, these data suggest that the low-voltage-activated current in MNTB neurons may be composed of a roughly equal mixture of channels containing Kv1.1 and Kv1.2, or Kv1.1 without Kv1.2, but possibly Kv1.6 (Dodson, P. D. *et al.*, 2002). The presence of other channels is not clear, although a compound that blocks Kv1.3 channels did not affect the current. Consistent with these data, immunostaining revealed Kv1.1, Kv1.2, Kv1.6, but not Kv1.4 or Kv1.5, in the MNTB (Dodson, P. D. *et al.*, 2002), and the high levels of Kv1.1 and Kv1.2 mRNA present in the MNTB by *in situ* hybridization (Grigg, J. J. *et al.*, 2000).

Further evidence regarding the contribution of Kv1.1 to the low-voltage-activated currents in the MNTB was obtained in a study of Kv1.1 knockout mice by Brew H. M. *et al.* (2003). In these mice, the low-voltage-activated current, as measured near threshold, was reduced in the knockouts, but not eliminated. DTX-I blocked about half of the current in both normal and knockout mice; the remaining current activated with a different time course and was not identified (although as it was not blocked by DTX-I, it appears to not be generated by Kv1 family channels). Nonetheless, in the knockouts, there was a substantial increase in the number of action potentials evoked during a rectangular current pulse. These results support not only Kv1.1 in MNTB neurons, but also show that in the absence of Kv1.1, Kv1.2, and/or Kv1.6 remain and generate a low-voltage-activated current. In this study, a small transient, rapidly inactivating current was also identified, although it appeared to be largely inactivated at rest.

The most detailed studies of the high-threshold current have been done on MNTB neurons. Both Kv3.1 and Kv3.3 are present in these cells by immunocytochemistry (Perney, T. M. *et al.*, 1992; Li, W. *et al.*, 2001) and by *in situ* hybridization (Wang, L. Y. *et al.*, 1998). A comparison of I_{HT} in MNTB neurons and Kv3.1 homomultimers in CHO cells (Wang, L. Y. *et al.*, 1998) shows that the currents are very similar. The similarity extends to the voltage dependence of the activation kinetics, and the magnitude of sensitivity to block by TEA. In these cells, the Kv3.1-like current contributes to action potential repolarization, and allows the cells to fire rapidly in response to trains of depolarizing current pulses (Wang, L. Y. *et al.*, 1998).

3.32.4.7 Medial Superior Olive

In terms of temporal precision, the neurons of the medial superior olive (MSO) have one of the most daunting tasks. These cells are responsible for comparing information from the two ears and generating a representation that the rest of the nervous system can use to make judgments about differences in sound arrival times that are on the order of 10 µs. The ion channels of MSO neurons are central to analyzing synaptic events with this level of temporal precision. It is not surprising then, that their discharge patterns

under current clamp is similar to that of bushy or MNTB neurons (Smith, P. H., 1995) (also, similar excitability is seen in the avian homolog, n. laminaris; Reyes, A. D. *et al.*, 1996). The conductance underlying this behavior was found first to be blocked by 4-AP (Smith, P. H., 1995), and subsequently by DTX-I and DTX-K (Svirskis, G., 2002; Scott, L. L. *et al.*, 2005), again implicating Kv1.1 and/or Kv1.2 channels in its generation. Similar observations have been made in n. laminaris (Kuba, H. *et al.*, 2002; 2005). While the general features of the conductances have been examined, so far no detailed kinetic analyses of the currents in these cells have been reported. Immunocytochemical analyses in both the MSO and n. laminaris support the presence of Kv1.1 and Kv1.2 channels. These cells also possess a high-threshold conductance that is revealed in the presence of DTX or 4-AP. Immunocytochemical analyses and *in situ* studies suggest that Kv3.3, rather than Kv3.1, may be responsible for this conductance in mammalian MSO (Li, W. *et al.*, 2001), although Kv3.1 is present in n. laminaris (Parameshwaran, S. *et al.*, 2001).

The operation of MSO and n. laminaris neurons as coincidence detectors in the traditional model (Jeffress, L. A., 1948) requires that the cells have a narrow temporal integration window. The presence of the low-voltage-activated conductance allows these cells to function as coincidence detectors of subthreshold inputs (Reyes, A. D. *et al.*, 1996; Kuba, H. *et al.*, 2005).

3.32.4.8 Other Auditory Structures

The conductances present in the principal nuclei involved in the processing of rapid timing information are recapitulated in other auditory brainstem nuclei, although in general less is known from a functional standpoint. Because, in general, these have not been investigated as extensively as the regions just discussed, they will be discussed as a group.

3.32.4.8.1 Superior olive

Nuclei that show high expression of Kv1.1 include scattered neurons in the ventral and lateral periolivary nuclei (Grigg, J. J. *et al.*, 2000; Rosenberger, M. H. *et al.*, 2003) and a few neurons in the LSO (Barnes-Davies, M. *et al.*, 2004); however, in general, the superior olive shows low levels of Kv1.2 (Grigg, J. J. *et al.*, 2000). HCN1 is highly visible in all nuclei of the SOC except the MNTB, whereas HCN2 is principally seen in the MNTB and the LSO (Koch, U. *et al.*, 2004). Kv3.1 is not highly expressed except in some cells of the superior paraolivary nucleus, whereas Kv3.3 appears to be widely expressed in all the principal nuclei and in surrounding periolivary cells (but see Grigg, J. J. *et al.*, 2000; Li, W. *et al.*, 2001). Most neurons of the superior olivary complex fire in a regular discharge pattern (Wu, S. H. and Kelly, J. B., 1991; Fujino, K. *et al.*, 1997; Adam, T. J. *et al.*, 1999; 2001; Barnes-Davies, M. *et al.*, 2004), although some neurons in the LSO (Barnes-Davies, M. *et al.*, 2004) and the lateral nucleus of the trapezoid body (Spirou, G. A. *et al.*, 1995) exhibit phasic responses and rectification.

3.32.4.8.2 Nuclei of the lateral lemniscus

Some, but not all, neurons of the ventral nucleus of the lateral lemniscus have phasic responses to current pulses (Wu, S. H., 1999) that are similar to those of VCN bushy neurons. Kv1.1 immunoreactivity is evident in this nucleus (Rosenberger, M. H. *et al.*, 2003), as is message for Kv3.1 and Kv3.3, and light immunostaining for Kv3.1 (Li, W. *et al.*, 2001). HCN1 and HCN2 are both found in the ventral nucleus also (Koch, U. *et al.*, 2004). Neurons in this nucleus can exhibit accurate onset timing in bats (Covey, E. and Casseday, J. H., 1991). The GABAergic neurons of the dorsal nucleus of the lateral lemniscus, in contrast, fire regular trains of action potentials (Wu, S. H. and Kelly, J. B., 1995). Kv3.1 and Kv3.3 are highly expressed as assayed by *in situ* hybridization (Li, W. *et al.*, 2001), and in bat in some neurons are lightly immunoreactive for Kv1.1 (Rosenberger, M. H. *et al.*, 2003).

3.32.4.8.3 Inferior colliculus

Neurons of the inferior colliculus can show a variety of sustained firing patterns to depolarization (Peruzzi, D. *et al.*, 2000; Sivaramakrishnan, S. and Oliver, D., 2001). However, a subset of cells show an onset response to current steps and an associated outward rectification (Wagner, T., 1994; Peruzzi, D. *et al.*, 2000) that is generated by a 4-AP-sensitive current (Sivaramakrishnan, S. and Oliver, D., 2001), and which allows the cells to follow higher rates of stimulation than other collicular neurons (Peruzzi, D. *et al.*, 2000). IC neurons express Kv3.1 and Kv3.3 at fairly high levels (Perney, T. M. *et al.*, 1992; Grigg, J. J. *et al.*, 2000; Li, W. *et al.*, 2001). Kv1.1 and Kv1.2 are also present (Grigg, J. J. *et al.*, 2000; Rosenberger, M. H. *et al.*, 2003), although some regional variation in expression patterns are evident. HCN1 and HCN2 are also both present (Koch, U. *et al.*, 2004).

There are hints that upper levels of the auditory system may have some specializations to improve temporal processing relative to neurons in nonauditory pathways. For example, action potentials of

thalamocortical recipient neurons in cat auditory cortex are narrower than those in similar neurons of the visual cortex (Smith, P. H. and Populin, L. C., 2001). In addition, GABAergic IPSPs have a faster time course in layer V neurons (Hefti, B. J. and Smith, P. H., 2003). Finally, at least during postnatal development, some auditory cortical neurons may have rectifying current–voltage relationships and phasic firing similar to the auditory brainstem neurons that convey timing information (Metherate, R. and Aramakis, V., 1999). Kv3.1 is highly expressed in auditory cortical interneuorns, apparently at higher levels than in surrounding regions (Li, W. *et al.*, 2001). The significance of these specializations is not known.

3.32.5 Summary of Channel Expression

As can be seen from the above review, there are several themes in the patterns of ion channel expression and discharge patterns in the auditory brainstem. Cells expressing low-voltage-activated potassium channels are present in circuits involved in processing timing information. These cells tend to fire a single action potential (or sometimes just a few action potentials) with step depolarization. Cells lacking this conductance are present in those auditory brainstem circuits that are not involved in processing precise timing information, and these cells tend to fire regular trains of action potentials. It is not clear to what extent these two motifs truly exist as canonical forms. Some evidence is consistent with the hypothesis that the expression of channels is in fact a continuum, with a graded variation of total conductance, and this may vary along to tonotopic axis, or even across tonotopic sheets of cells. The idea that there is a tonotopic distribution of conductances is supported by several lines of recent evidence, and is discussed later.

Because of the bifurcation of the cell voltage trajectory that results from the nonlinear interactions of the sodium and potassium channels over time, cells with similar qualitative but quantitatively different channel expression can show different firing patterns. For example, expression of the low-voltage-activated K^+ currents is not sufficient to make a cell fire phasically at all current levels. If a cell has relatively weak low-voltage-activated potassium conductance, it might fire phasically only for weak current injections that are just suprathreshold for an AP, but larger current injections could be sufficient to counter the outward current and push the cell into a repetitive firing mode (Rothman, J. S. and Manis, P. B., 2003b). Current clamp recordings in the VCN and MNTB have consistently shown (in mice, rats, and guinea-pigs, e.g., see Oertel, D., 1983; Francis, H. W. and Manis, P. B., 2000) that some cells fire with a type II phasic pattern of a single action potential for weak currents can generate a short, although not sustained, train of repetitive spikes for larger currents. Thus, the simple expression of channel transcripts is not sufficient for the elaboration of a particular discharge pattern; both the density and distribution of the channels in the membrane play a critical role. These two factors are difficult to measure accurately.

3.32.6 The Role of Low-Voltage-Activated K^+ Channels in Temporal Integration

The low-voltage-activated K^+ channels play several roles in the temporal integration of synaptic inputs in auditory neurons (Trussell, L. O., 1999). Each of these roles serves to enhance the ability of the cells to fire precisely timed action potentials in response to afferent activity. The first role is as a conductance shunt. Because it is generally found that the low-voltage-activated channels are partially conducting at rest, they participate in both setting the resting potential and in setting the membrane conductance (and therefore, time constant). Estimates of the fraction of channels open at rest in cochlear nucleus neurons vary from 10% to 15%, based on calculations using Boltzman fits to the voltage dependence of the conductance in mammals (Manis, P. and Marx, S., 1991; Bal, R. and Oertel, D., 2001; Rothman, J. S and Manis, P. B., 2003a), to about 30% in avian n. magnocellularis (Rathouz, M. and Trussell, L., 1998). The conductance contributed by the low-voltage-activated channels at rest then corresponds to 20–60 nS, which can be nearly as large as the resting conductance of the cell. This conductance may also be balanced by the conductance of I_H channels, which are of similar magnitude at rest in octopus cells (Bal, R. and Oertel, D., 2000). This is also on the same order of magnitude as the conductance contributed by single endbulb of held synapses in mouse VCN (a typical single auditory nerve fibre (ANF) input generating a 5 nA excitatory postsynaptic currents (EPSCs) at −60 mV in mouse VCN bushy cells (Wang, Y. and Manis, P. B., 2005) would correspond to 83 nS). Because the membrane time constant is short, the synaptic conductance can charge and discharge the

cell membrane very rapidly; thus the excitatory postsynaptic potential (EPSP) is not much longer than the duration of the synaptic conductance, and the conductances themselves are very brief (Trussell, L. O., 1999). In addition, this shunting effect limits the window for temporal summation of subthreshold EPSPs, so that close temporal coincidence of subthreshold events is necessary to reach threshold; this can enhance temporal precision by averaging inputs to the cell and may be responsible for the ability of some cells to show greater phase locking than their inputs (Rothman, J. and Young, E., 1996).

Second, the low-voltage-activated channel limits extra action potentials that might be produced by strong excitatory inputs (Brew, H. M. and Forsythe, I. D., 1995; Gittelman, J. X. and Tempel, B. L., 2006). This occurs because the conductance activates during action potentials, and so contributes to action potential repolarization (Rothman, J. S. and Manis, P. B., 2003b; Klug, A. and Trussell, L. O., 2006). Limiting extraneous action potentials in response to a cyclical input (click train or tones) would improve temporal signaling, especially when this signaling is compared to that of other neurons responding to the same temporal pattern of input, and is analyzed by higher-order neurons receiving convergent input. Suppression of multiple action potentials would also maximize the opportunity for action potentials to be phase locked to subsequent cycles of a tonal stimulus, and would reduce the refractory period by providing additional hyperpolarization between cycles. A similar role for these channels in the presynaptic terminal has been shown (Dodson, P. D. *et al.*, 2003). In this context, the high- and low-voltage-activated currents are likely to interact during periods of high synaptic drive to promote sustained and temporally precise high rate firing (Fernandez, F. R. *et al.*, 2005; Klug, A. and Trussell, L. O., 2006).

Third, the low-voltage-activated channels makes the cells more sensitive to rapidly changing events than to slowly changing events; in other words, they become sensitive to the slope of the EPSP, such that rapidly rising EPSPs have a much higher probability of bringing the cell to threshold than slowly rising events (Ferragamo, M. J. and Oertel, D., 2002; McGinley, M. J. and Oertel, D., 2006). The slope sensitivity arises in part because activating the low-voltage-activated conductance can raise spike threshold (Brew, H. M. *et al.*, 2003; see also Fukui, I. and Ohmori, H., 2004), and in part because slowly rising EPSPs will allow the low-voltage-activated conductance to turn on before the peak of the EPSP, which reduces the amplitude of the EPSP. In contrast, rapidly rising events bring the cell to threshold before the low-voltage-activated currents become fully activated. In the case of octopus cells, this allows the cells to respond to synchronous synaptic inputs with precisely timed action potentials, but will tend to suppress responses to desynchronized inputs (Ferragamo, M. J. and Oertel, D., 2002; McGinley, M. J. and Oertel, D., 2006). The slope sensitivity varies among cells in the VCN that express different amounts of low-voltage-activated conductances (McGinley, M. J. and Oertel, D., 2006). The way in which these channels impart slope sensitivity will depend on their rates of activation. Although the low-voltage-activated channel activates with fourth-order kinetics, at a resting potential of −60 mV the energetics are such that the channels need only move through a single gating transition to achieve the open state (Rothman, J. S. and Manis, P. B., 2003a). Thus, at rest, they will open with first-order kinetics with no delay (Manis, P. and Marx, S., 1991; Rathouz, M. and Trussell, L., 1998; Rothman, J. S. and Manis, P. B., 2003a), so that they will be engaged at the first sign of depolarization. A covariance analysis of the membrane potential preceding spikes in n. magnocellularis was undertaken to examine the temporal nonlinearities present in these cells (Slee, S. J. *et al.*, 2005). Spike generation depended on two features of the input: a short-term (2 ms wide) smoothing function and a short-term (<5 ms wide) derivative-like function. Sensitivity to the derivative-like function was largely abolished with the low-voltage-activated conductance was blocked with α-DTX, whereas the short-term smoothing component remained. This analysis thus supports the contention that the low-voltage-activated conductance confers sensitivity to rapidly fluctuating voltage changes, rather than the time-averaged membrane potential.

Fourth, activation of the low-voltage-activated channels can improve the signal-to-noise ratio for detection of weak excitatory events against a background of uncorrelated activity (Svirskis, G., 2002; Svirskis, G. *et al.*, 2004). These authors used dynamic clamp to simulate synaptic conductances onto MSO neurons. The contribution of the low-voltage-activated channels to signal detection was found to be twofold. First, reducing the low-voltage-activated current with DTX reduced the synchrony of the response to specific, slightly larger, inputs, largely because decreasing the conductance permitted weaker, uncorrelated, inputs to generate extraneous spikes. Second, using reverse correlation (spike-triggered averaging), it was found that the average

synaptic current that brought the cell to threshold was rapidly rising (see also Slee, S. J. *et al.*, 2005), and that in the presence of DTX, more slowly rising events could also be effective. These properties are consistent with results described above for MNTB principal neurons, n. magnocellularis neurons, and cochlear nucleus octopus cells.

Together, these features suggest that low-voltage-activated potassium conductances optimize detection of rapidly changing synchronous synaptic input (whether from a few or many synapses), while simultaneously suppressing the contributions of asynchronous and slow inputs, and suppressing asynchronous postsynaptic spikes. Which contribution is most important for processing for a given cell type seems to depend on the pattern of afferent convergence, and perhaps the relative size of the low-voltage-activated conductance.

3.32.6.1 Tonotopic Channel Expression Patterns, and Relationship to Integrative Roles

The fundamental organizing principle of the auditory system is the representation of sound frequency as position (tonotopic organization). In many species, there are clear and well-established gradients of cellular mechanisms along the tonotopic axis in the auditory end organs (cochlea and basilar papilla) that support the temporal requirements for sensory processing of different frequency sounds (Fettiplace, R. and Fuchs, P. A., 1999). Such gradients make sense for peripheral processing. Perhaps not surprisingly, similar gradients have been described in central nuclei, even though their existence might not be predicted to be necessary. Because sound is converted into a train of action potentials at the level of the auditory nerve, the sound frequency itself is no longer represented in terms of a continuously variable signal. Instead, frequency is represented as the place of activity, and other attributes such as intensity or stimulus phase are encoded in action potential intervals in single fibers or as temporally correlated firing across fibers. The information represented by these action potentials is, in some senses, independent of acoustic stimulus frequency. However, both the tonotopic variation in ion channel expression in the SGCs (discussed above), and the variation in the precision of temporal structure in ANF responses to broadband noise suggests that ANFs represent other kinds of temporal information that do change with tonotopic position. For example, the temporal dispersion of spike times sufficient to attain a vector strength of 0.9 at 500 Hz is much greater than the dispersion necessary to attain a lower vector strength at 2 kHz (Koppl, C., 1997; Paolini, A. G. *et al.*, 2001); hence, the temporal requirements for detection of correlated afferent activity are more stringent for high-frequency cells. Finally, phase locking in the low-frequency tail of cat high characteristic frequency (CF) ANF response areas is better than the phase locking seen at the same frequencies, near CF, for low-frequency ANFs (Joris, P. X. *et al.*, 1994), which suggests that timing information in high CF fibers is more precise than in low CF fibers. This is also reflected in the temporal correlations in response to broadband noise. The interstimulus correlations of responses to noise in cat ANFs show a central peak whose width varies from about 1 ms for 4 kHz fibers to 400 μs for 12 kHz fibers (Louage, D. H. *et al.*, 2004). Translating this into the response of many fibers of a given CF to the same stimulus, it suggests that certain features of the stimulus generate correlations in synaptic input whose relative timing is in the 1–0.4 ms range, depending on CF. Postsynaptic cells that receive subthreshold inputs (globular bushy cells and octopus cells) could detect these coincident synaptic events and forward this information to higher-order nuclei.

Tonotopic gradients in cellular mechanisms of information processing are present in some central auditory nuclei. High levels of Kv3.1 immunostaining are seen in the high-frequency regions of the avian n. magnocellularis and n. laminaris (Parameshwaran, S. *et al.*, 2001). A similar gradient of Kv3.1 expression is present along the tonotopic axis of the rat and mouse MNTB (Li, W. *et al.*, 2001; von Hehn, C. A. *et al.*, 2004) and possibly VCN (von Hehn, C. A. *et al.*, 2004). Because Kv3.1 is a high-threshold delayed rectifier channel, it is largely involved in action potential repolarization (Rothman, J. S. and Manis, P. B., 2003b; Klug, A. and Trussell, L. O., 2006). Thus, the gradient suggests that the high-frequency cells might recover from a spike more rapidly and could have greater firing precision for high afferent rates. However it is unclear why the low-frequency cells do not have a similar expression level; it is possible that they utilize another channel. Physiological measurements in the MNTB are consistent with this, revealing a gradient in the low- and high-voltage-activated K^+ conductances (largest conductance in the high-frequency regions), whereas an unidentified K^+ conductance showed an opposing gradient (Brew, H. M. and Forsythe, I. D., 2005). In n. magnocellularis, there is higher Kv1.1 expression in the high-frequency regions, which correlates well with the intrinsic physiology of the cells

(Fukui, I. and Ohmori, H., 2004). The higher expression of Kv1.1 endows the high-frequency cells with shorter time constants, and a shorter window for coincidence detection. This kind of gradient is also consistent with the smaller timing dispersion for afferent synapses from high-frequency regions of the basilar papilla (Koppl, C., 1997). In n. laminaris, which expresses Kv1.1 at a lower level than Kv1.2, Kv1.2 is found to be maximal in the middle region, and lower at higher and lower frequencies (Kuba, H. *et al.*, 2005). This is also consistent with cells in the mid-frequency region having shorter time constants, lower input resistances, and more rapidly decaying EPSPs (however, cf. Reyes, A. D. *et al.*, 1996). In rat LSO, Kv1.1 protein and low-voltage-activated conductance expression are higher in the low-frequency regions (Barnes-Davies, M. *et al.*, 2004). With the exceptions of the LSO and n. laminaris, the central K^+ channel gradients follow a general pattern similar to that reported for the SGC: Kv1.1 (or Kv1.2) and Kv3.1 are more highly expressed in the higher-frequency neurons. Thus, it appears that the biophysical mechanisms that support fine temporal processing are optimized to match the tonotopic variation in the precision of afferent spikes.

3.32.7 Conclusion

Many neurons of the auditory system are specialized for rapid temporal processing. Although the specific mechanisms that participate in the analysis of timing information are most evident in the brainstem, there is also evidence that some specialization in terms of receptors and channels may be present even in primary auditory cortex. The key elements appear to be combinations of voltage-gated potassium and hyperpolarizatation-activated conductances that appear as repeated motifs in the cells involved in temporal processing. These include low-voltage-activated potassium channels that operate in a subthreshold voltage regime to determine the rules of synaptic integration as well as participate in dynamically regulating spike threshold, hyperpolarization-activated cation channels that presumably control the level of activation of the subthreshold potassium conductances and perhaps the availability of sodium conductances, and high-voltage-activated potassium channels that rapidly repolarize action potentials and support the ability of the cells to fire precisely timed spikes at high rates. These combinations are seen both in avians and mammals, attesting to their fundamental importance in auditory temporal processing. Many of the neurons with these channel combinations were once thought to operate as relays that forwarded temporal information with little modification. However, this is clearly not an accurate depiction of their operation, as the cells do not fire in response to all afferent spikes (Li, R.Y.-S. and Guinan, J. J., 1966; Kopp-Scheinpflug, C. *et al.*, 2002; 2003). Temporal processing in these cells is influenced by many additional processes, such as synaptic depression (Brenowitz, S. and Trussell, L., 1998; Cook, D. L. *et al.*, 2003), contributions from dendritic and electrotonic structure (Agmon-Snir, H. *et al.*, 1998; Zhou, Y. *et al.*, 2005), regulation by neuromodulators (Kossl, M. and Vater, M., 1989; Banks, M. I. *et al.*, 1993), and of course, inhibition (Caspary, D. M., *et al.*, 1994; Grothe, B. and Sanes, D. H., 1994; Brand, A. *et al.*, 2002; Kopp-Scheinpflug, C. *et al.*, 2002). It is the dynamic interaction between all of these influences and the different sets of ion channels that ultimately determines the exquisite temporal acuity of the auditory system.

Glossary

action potential or spike Unit electrical signal in the functioning nervous system.

AMPA receptor Glutamate receptors which selectively bind the drug alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA). These are the major excitatory postsynaptic receptors in the vertebrate central nervous system.

calyx synapse Very large terminals of globular bushy cell axons onto principle cells of the medial nucleus of the trapezoid body (MNTB).

endbulb synapse Large terminals of auditory nerve fibers onto spherical bushy cells in the cochlear nucleus.

EPSC Excitatory postsynaptic current, the excitatory current flow through transmitter receptor/channels such as AMPA or NMDA receptors.

EPSP Excitatory postsynaptic potential, the potential generated as the EPSC discharges the postsynaptic membrane.

exocytosis Secretion of neurotransmitter by fusion of transmitter-filled vesicles with the presynaptic plasma membrane.

GABA receptor Receptor for the inhibitory transmitter gamma-aminobutyric acid (GABA).

glycine receptor Receptor for the inhibitory transmitter glycine.

intrinsic response properties A neuron's stereotyped response to a given stimulus as a consequence of its geometrical arrangement and the complement of voltage-gated ion channels it expresses.

IPSP Inhibitory postsynaptic potential, the potential change due to anionic current flow through GABA or glycine receptor channels.

NMDA receptor Glutamate receptors which selectively bind the drug *N*-methyl-D-aspartic acid (NMDA).

release site Equivalent to active zone, the region of the presynaptic membrane from which transmitter is exocytosed.

3.33.1 Introduction

The central nervous system (CNS) must preserve and detect the timing of action potentials, or spikes, in the auditory nerve in order to localize sounds and to understand complex spectral information encoded in vocalizations. For example, spike timing in different fibers must at some point translate to a neural map for sound location relative to head position. The timing must be preserved along the pathway until the point at which the map is laid out. In localization of sound in the horizontal plane, phase shifts of tens of microseconds between sounds at the two ears changes significantly the perceived location of the sound source (Carr, C. E., 1986). Thus, acoustically driven spikes conducted along sequential neural stations must have minimal trial-to-trial error in their timing. Moreover, conduction through synaptic relays must be very fast, to enable precise convergence of signals from different nerve fibers, and so that a rapid succession of information can be processed. This dual requirement for precision and speed places special demands upon synapses in the auditory system. While the speed of conduction in nerve fibers is a problem solved by myelinated axons throughout the nervous system, precise and rapid synaptic transmission has required special refinements of physiology and morphology. This chapter will explore these refinements in some of the major cell types associated with acoustic timing pathways.

3.33.2 Synaptic Transmission

First, it may be helpful to review some of the basic elements of synaptic function, in order to appreciate better the unique adaptations in auditory synapses. Readers unfamiliar with this topic are also encouraged to consult well-known textbooks for a more complete account (e.g., Nicholls, J. G. *et al.*, 2001). Those trained in cellular neuroscience may skip ahead.

Classical central synapses formed between two neurons usually consist of just a few synapses or boutons, each one a site for exocytosis of the chemical transmitter from synaptic vesicles (Figure 1). For most vertebrate excitatory synapses, that transmitter is the amino acid glutamate, and the postsynaptic receptors that detect the glutamate are of two types, the alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptor and the *N*-methyl-D-aspartic acid (NMDA) receptor. These subtypes are distinguished by their pharmacological sensitivities, their timecourse or kinetics of activation, and the change in ion permeability they induce in the postsynaptic cell (Dingledine, R. *et al.*, 1999). There are other types of glutamate receptors, but these will not be discussed here. Arrival of an action potential at the nerve terminals leads to a rapid elevation of presynaptic intracellular Ca^{2+}, which then triggers exocytosis of the transmitter. Figure 2 details the steps involved in transmission. At most synapses, the delay between the presynaptic spike and the onset of the postsynaptic response to the transmitter is 0.5 ms or less. Each synaptic site typically liberates one or fewer synaptic vesicles per presynaptic spike, which is to say that the probability of release at each site is between zero and one. Thus, the effectiveness of transmission can be increased by having more synaptic sites (i.e., more boutons), higher release probability at each site, or by increasing the number of receptors available to respond to the transmitter. A

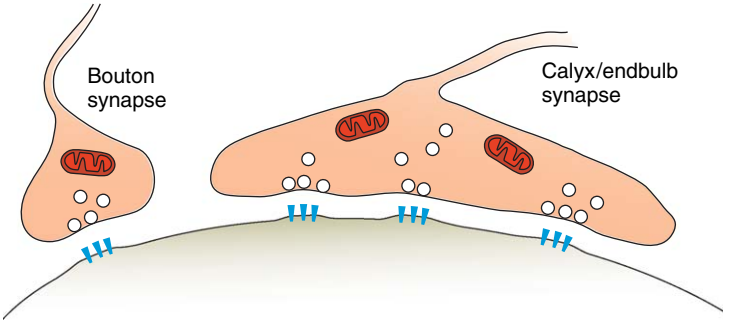

Figure 1 Two types of excitatory synapses that preserve spike timing that are found in auditory pathways. Bouton terminals have only one or two sites of transmitter release, each with a few docked vesicles. Calyceal and endbulb terminals feature a large number of transmitter release sites. In all cases, the transmitter is glutamate, which mediates its effect by binding postsynaptic alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptors.

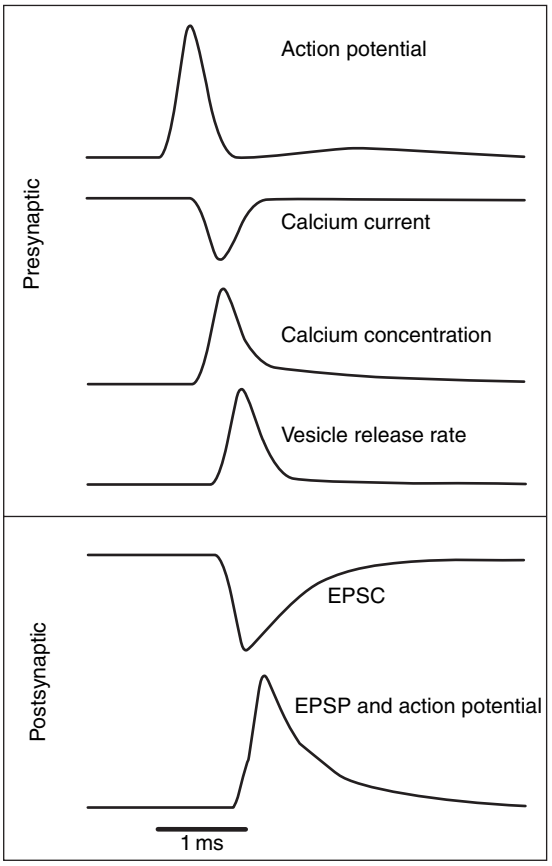

Figure 2 The steps involved in chemical synaptic transmission. Arrival of an action potential in the axon terminal triggers an inward calcium current and a rise in intraterminal calcium levels. This rise in calcium triggers a sharp increase in the rate of exocytosis, releasing the contents of synaptic vesicles into the synaptic cleft. The transmitter binds and activates postsynaptic receptors, generating an inward, excitatory current, the EPSC. The resulting depolarization is the EPSP, which drives the membrane potential past threshold for triggering an action potential. The time between the peak of the pre- and postsynaptic spikes can be less than 1 ms.

similar scenario holds for the major inhibitory transmitters gamma-aminobutyric acid (GABA) and glycine. Generally, a single vesicle's worth of glutamate has little depolarizing power to trigger a postsynaptic spike, but when many synapses are simultaneously active, summation of the depolarizing response occurs, and brings the postsynaptic membrane potential across spike threshold. Often, activation of many presynaptic neurons (each making several synaptic boutons) is required to trigger a postsynaptic spike, although there are well known cases where activation of a single presynaptic axon is sufficient, as described below.

Following the activation of the glutamate receptors, positive ionic current flows into the postsynaptic cell (EPSC), leading to membrane depolarization (EPSP). However, the consequence of this depolarization, in terms of the timing and pattern of spikes, varies dramatically in different types of neurons. This topic is explored in the chapter on Biophysical Specializations of Neurons that Encode Timing, by Paul B. Manis, and so only a brief overview will be made. Synaptic depolarization is limited in size and shape by the intrinsic electrical resistance and capacitance of the cell membrane. This resistive property, generated by an assortment of membrane ion channels, is highly nonlinear, with strong voltage and time dependencies. The morphology of the cell also plays a significant role; when synapses are made onto dendrites, the electrical filtering that is produced by dendrites typically leads to distortion of synaptic responses as the signals pass to the cell body and the axonal spike-trigger regions (Stuart, G. *et al.*, 1999). Because of these factors, a cell's shape, location of synapses, and the exact complement and distribution of ion channels are key determinants of the response to activation of the postsynaptic receptors.

3.33.3 Overview of the Types and Morphology of Synapses in Auditory Pathways

In this overview, we will focus primarily on a subset of auditory brainstem synapses within the sound localization pathways. Later we will consider the properties of these synapses in more detail and also in relation to that of the hair cell synapse, the site at which timing information is first encoded as neuronal action potentials. Readers should also consult the chapter on Afferent Synaptic Mechanisms by William Roberts.

Action potentials arrive at nerve terminals in the cochlear nucleus via the highly branched auditory nerve fibers. This branching accomplishes a division of information into multiple parallel pathways for computation (Cant, N. B. and Benson, C. G., 2003). For example, in the mammalian ventral cochlear nucleus (VCN), auditory nerve terminals onto the large spherical bushy cells initiate a pathway involved in localization of sounds along the azimuth using interaural timing cues. In birds, spherical bushy cells are the principal cells of the nucleus magnocellularis (NM). Terminals on the small spherical and globular bushy cells of mammals initiate azimuthal

localization by interaural intensity cues (Oertel, D., 1999; Cant, N. B. and Benson, C. G. 2003). In the mammalian dorsal cochlear nucleus (DCN), auditory nerve terminals onto fusiform neurons are believed to play a role in sound localization-based monaural spectral cues (Oertel, D. and Young, E. D., 2004). As discussed below, the different synapses made by the auditory nerve are diverse in both morphology and physiological mechanisms, in keeping with their different roles in information transfer. Figure 3 diagrams the major regions and cell types discussed in this chapter.

3.33.3.1 Bushy Cells and the Endbulbs of Held

Auditory nerve terminals onto large spherical bushy cells are called endbulbs of Held. Unlike classical boutons, each endbulb is a collection of hundreds to thousands of synaptic release sites distributed among thick fingers and fine branchlets of a terminal that enshrouds the postsynaptic cell body (Cant, N. B. and Morest, D. K., 1979; Ryugo, D. K. *et al.*, 1996; Nicol, M. J. and Walmsley, B., 2002; Figure 4). Each large spherical bushy cell typically receives one to three such terminals, and activation of each endbulb can

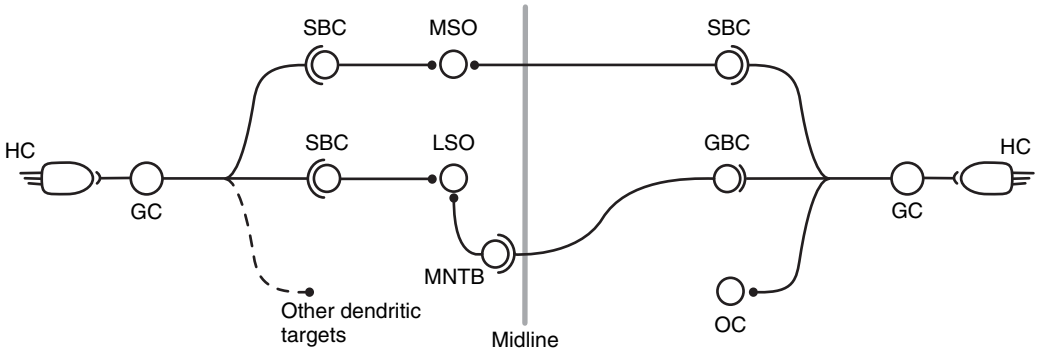

Figure 3 Diagram of the primary mammalian cell types, brain regions, and interconnections discussed in this review. GBC, globular bushy cell; GC, ganglion cell; HC, hair cell; LSO, lateral superior olive; MNTB, medial nucleus of the trapezoid body; MSO, medial superior olive; OC, octopus cell; SBC, spherical bushy cell.

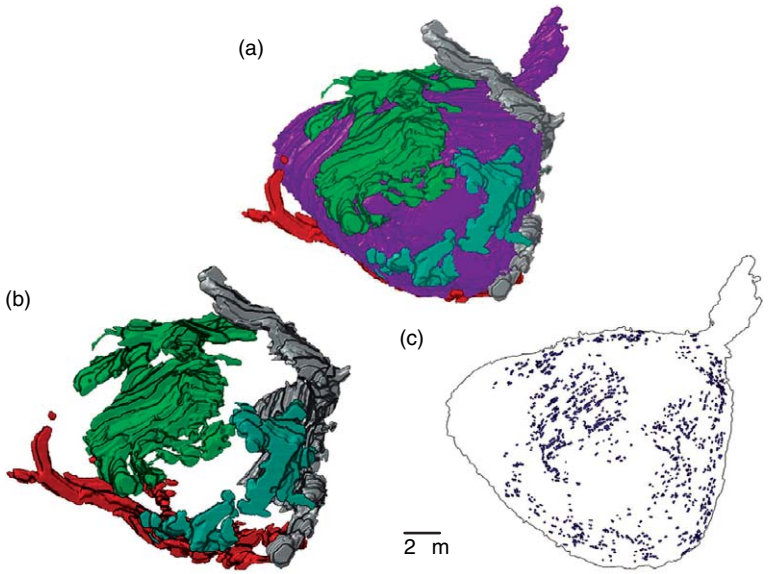

Figure 4 Electron microscopic reconstruction of four endbulbs terminating on a single bushy cell from the rat. (a) Each endbulb is in a different color; the postsynaptic neuron is shaded purple; (b) the postsynaptic cell is removed to show how the endbulbs enshroud the cell surface; (c) the postsynaptic cell is outlined and the location of synaptic release sites is indicated by the spots. Figure adapted from the study of Nicol M. J. and Walmsley B. (2002). with permission.

reliably trigger postsynaptic spikes. Accordingly, spherical bushy cells show a response pattern to tonal inputs similar to that of auditory nerve fibers (Rhode, W. S. *et al.*, 1983). This is characterized in a peristimulus time histogram (PSTH), which plots the frequency of spiking during a stimulus. Such plots for spherical bushy cells or auditory nerve show, for low-frequency sounds stimuli, peaks in activity associated with the phase of the sound. This concentration of the response within the phase of the sound wave cycle is called phase locking. For higher-frequency stimuli, beyond about 2 kHz, phase locking is lost both pre- and postsynaptically; after an initial well-timed spike, subsequent activity occurs randomly with respect to sound, but at an average rate reflecting the intensity of the sound energy (Joris, P. X. *et al.*, 1994). Because of this matching of pre- and postsynaptic spike behavior (Pfeiffer, R. R., 1966), large endbulb synapses are often characterized as synaptic relays.

The gross morphology of endbulbs has been shown to vary with the activity level of the presynaptic fiber. Endbulbs of genetically deaf cats and mice, for example, are characterized by an increase in the complexity of the synapse's branchlets as compared to conspecifics with normal hearing (Ryugo, D. K. *et al.*, 1997; Lee, D. J. *et al.*, 2003). Some studies indicate that this morphological pattern is paralleled by physiological changes in the strength of transmission, although this effect seems to vary with the genetic model (Oleskevich, S. *et al.*, 2004; Wang, Y. and Manis, P. B., 2005). Differences in morphology are also associated with the average activity level of the auditory nerve fiber, such that axons that have higher spontaneous (background) activity levels make synapses of simpler morphology (Sento, S. and Ryugo, D. K., 1989). In avian bushy cells, neurons in the regions receiving signals from higher-frequency sound information (i.e., high characteristic frequency) have larger, simpler terminals and fewer endbulbs per cell body (Koppl, C., 1994; Fukui, I. and Ohmori, H., 2004). Thus, these data suggest the possibility that the endbulb may dynamically adjust for changing average levels of acoustic stimulation.

In contrast to the spherical cells that host the large endbulbs, globular bushy cells are believed to be contacted by up to 30 auditory nerve terminals (Smith, P. H. and Rhode, W. S., 1987; Liberman, M. C., 1991). While the so-called modified endbulbs are, like the large endbulbs, confined mainly to the cell body, their smaller size means that each terminal has less influence, by itself, on postsynaptic cell firing. As a result, globular bushy cells probably fire only when multiple presynaptic fibers are synchronously active (Rothman, J. S. *et al.*, 1993; Joris, P. X. *et al.*, 1994). Such a mechanism has the ability to reduce the jitter in the firing of signals relative to the phase of the sound source. Indeed, the firing of globular bushy cells, measured by recordings made from their axons in the trapezoid body, show significant improvements in spike timing relative to that of auditory nerve fibers (Joris, P. X. *et al.*, 1994). For these cells, the peristimulus time histogram of the response to low-frequency sound is characterized by very narrow peaks around the phase of the sound cycle. With higher sound frequencies, an extremely well-timed initial spike is followed by a pause in firing, perhaps due to the spike refractory period of the fibers, and then a much lower level of randomized firing (Smith, P. H. and Rhode, W. S., 1987).

3.33.4 Medial Nucleus of the Trapezoid Body

The very large axons of globular bushy cells terminate on the principal cells of the medial nucleus of the trapezoid body (MNTB) as calyces of Held, among the largest synaptic terminals in the mammalian brain. Each principal cell receives only one such calyx, which occupies nearly half of the cell body surface (Smith, P. H. *et al.*, 1998; Satzler, K. *et al.*, 2002). Calyces, like endbulbs, are riddled with synaptic release sites; in the rat, each terminal contains over 600 active zones (Meyer, A. C. *et al.*, 2001; Satzler, K. *et al.*, 2002; Taschenberger, H. *et al.*, 2002), more than enough to drive the postsynaptic cell quickly to spike threshold (Taschenberger, H. and von Gersdorff, H. 2000). Calyces are therefore the ultimate synaptic relay, and accordingly the firing of principal cells generally follows closely that of calyces (Guinan, J. J., Jr. and Li, R. Y., 1990). As these synapses must quickly ferry signals from the contralateral bushy cells to the ipsilateral lateral superior olive (LSO), all aspects of the axons and synapse are suited to minimizing delays. Indeed, the time delay for signals to travel through this pathway, as compared for signals between ipsilateral cochlear nucleus and LSO, is less than 0.2 ms in cats (Joris, P. X. and Yin, T. C., 1998). In the later sections we will examine more carefully the functional differences between calyces and endbulbs, and possible modifications to their relay function.

3.33.5 Dendritic Coincidence Detectors

Many cell types in the cochlear nucleus and superior olive receive synaptic inputs on dendrites, rather than on (or in addition to) their cell bodies; for some of these cells, their spike output is highest when their inputs fire in precise synchrony. Such coincidence detectors include the octopus cells of the posteroventral cochlear nucleus and the principal cells of the medial superior olive (or its avian homolog, the nucleus laminaris (NL)). Octopus cells receive auditory nerve inputs representing a broad range of frequencies, an exception to the rule of highly frequency-specific, tonotopic innervation of other auditory brainstem neurons (Golding, N. L. *et al.*, 1995). Octopus cells will fire only in response to synchronous activation of groups of synaptic inputs, a feature well suited for the detection of acoustic elements of speech (Oertel, D. *et al.*, 2000). However, because so many axons contact these cells, and not all need fire to drive the cell to threshold, the firing of octopus cells can entrain to higher-frequency sounds, firing on a one-to-one basis with the sound cycle up to nearly 1 kHz (Rhode, W. S. and Smith, P. H., 1986; Oertel, D. *et al.*, 2000). In terms of both precision and entrainment, they are among the most specialized cells in the mammalian nervous system.

Bipolar or bitufted neurons of the mammalian medial superior olive/avian NL receive frequency-specific inputs segregated onto their two dendritic fields, physically segregating the inputs from ipsi- and contralateral spherical bushy cells. According to classical models of sound localization, the precise convergence of ipsi- and contralateral excitatory inputs forms the basis for encoding interaural time delays ((Joris, P. X. *et al.*, 1998) see chapter by E. Rubel). More recent models suggest an important role for precise convergence of inhibitory inputs as well as excitatory inputs, at least in mammals (Brand A. *et al.*, 2002). In any case, it is thought that the ability of these cells to fire only when their synaptic inputs are well timed (with submillisecond accuracy) is an essential feature of their role in sound localization.

With these examples we have a paradox. Why is it that endbulbs and calyces of Held require large somatic synapses for their role in timing circuits, yet octopus and medial superior olive (MSO)/laminaris cells are able to function with small synapses on dendrites? Several aspects of this question are worth investigating. The role of large synapses is very different from that of coincidence detectors, namely to permit one or a few axons to exert complete control over the firing of the postsynaptic cell and to relay signals quickly. Large somatic synapses enable presynaptic axons to drive the postsynaptic cell to threshold reliably and without much delay. By contrast, coincidence detectors function through precise integration of well-timed signals. Some physiological features are common to all of these synapses, for example the types of synaptic receptors and ion channels that are employed. Still, it is not clear how fast, reliable timing information can be encoded in cells with dendrites. Some clues may be found in the fact that the dendrites are not particularly long, and can be rather stout, conditions that certainly minimize distortions of signals by electrical cable effects. One extreme example is in medial regions of the avian NL, in which cells have dozens of remarkably short dendrites, resembling the roots of a green onion (Smith, D. J. and Rubel, E. W., 1979; Carr, C. E. and Konishi, M., 1990). Dispersing synaptic inputs onto different dendrites has been proposed to favor the integration of synaptic signals between dendrites rather than within a dendrite (Agmon-Snir, H. *et al.*, 1998). This is because when adjacent synapses are active, the local depolarization they generate will tend to reduce the electrical driving force for synaptic current flow; synapses far away from one another will therefore tend to contribute to more effectively to depolarization of the soma and nearby spike generating regions. Other factors need to be investigated, however, such as unusual distributions of ion channels, which might shape the electrical profile of dendritic responses. Critically timed inhibition may also play an important role in this process (Brand, A. *et al.*, 2002; Zhou, Y. *et al.*, 2005).

3.33.6 Transmission at Giant Synapses

In this section we will focus on the properties of giant synapses, in part because they represent the quintessential spike timing relay, but also because their large size has made them particularly amenable to biophysical and molecular analyses. Many of their detailed, physiological, features are probably common to all of the synapses described above. Most of the attention to presynaptic function has taken advantage of the calyx of Held, and therefore this will be described most extensively below. However, where appropriate, information derived from studies of endbulb synapses will also be included.

3.33.7 Synaptic Strength at Auditory Relays

The hallmark of endbulb and calyceal synapses is their size. As noted above, electron microscopic reconstructions indicate that each terminal probably contains at least 600 synaptic active zones. At each active zone, two to seven vesicles are touching the plasma membrane; these are termed docked vesicles and it is assumed that any of these is available for exocytosis (Satzler, K. *et al.*, 2002; Taschenberger, H. *et al.*, 2002). Thus, one may conclude that the pool of releasable vesicles numbers in the thousands. This estimate roughly coincides with several physiological estimates of the readily releasable pool, although the definition of this pool remains highly method-dependent (Sun, J. Y. and Wu, X. S., 2001).

For low-frequency calyceal stimuli, the quantal content (evoked EPSC/miniature EPSC (mEPSC)) of each EPSC is about 200–400, indicating that only a fraction (presumably a random fraction) of release sites and vesicles are used in each response (Zhang, S. and Trussell, L. O., 1994b; Iwasaki, S. and Takahashi, T., 2001). Still higher estimates of spike-evoked release come from measurements of presynaptic capacitance during exocytosis (Taschenberger, H. *et al.*, 2002; Sun, J. Y. *et al.*, 2004). To view the vesicle pool size and quantal content with respect to what the synapse needs for effective transmission, we should consider the depolarizing power of a vesicle's worth of glutamate. The response to the release of one vesicle of glutamate results in 30–50 pA of current at a membrane potential of −70 mV (Sahara, Y. and Takahashi, T., 2001); this in turn may depolarize the membrane by roughly 1 mV. With spike threshold of only about 20 mV positive to the resting potential (Awatramani, G. B. *et al.*, 2004), the number of released vesicles needed to trigger a spike is relatively small. Even though nonlinearities in summation of synaptic currents and in membrane conductance will increase the quantal number needed to reach threshold, these data indicate that the calyx releases many more vesicles than are needed to reach spike threshold. This surplus is evident in experiments on endbulbs which showed that release could be blocked by over 80% and reliable transmission is still maintained (Brenowitz, S. *et al.*, 1998). Such a high safety factor is not only an insurance policy for suprathreshold transmission. Large synaptic currents drive the postsynaptic cell to threshold sooner than small currents; thus, a high safety factor ensures that spike latencies and jitter is small (see the section Reliablity of Timing).

The rapid termination of the transmitter release process is essential to high-frequency transmission. Experiments in which voltage clamp stimuli of variable duration were delivered to the nerve terminals demonstrated that the release process could be critically shaped by the waveform of the presynaptic spike (Borst, J. G. and Sakmann, B., 1999; Fedchyshyn, M. J. and Wang, L. Y., 2005). Spike width is tightly regulated during brain development. Between postnatal ages 7 and 14, the duration of the EPSC becomes significantly shorter, and parallels an age-dependent narrowing of the presynaptic spike (Taschenberger, H. and von Gersdorff, H., 2000). Presumably, enhanced expression in mature animals of presynaptic K^+ currents that repolarize the spike is key to the fast performance of this synapse (Dodson, P. D. *et al.*, 2003; Ishikawa, S. *et al.*, 2003).

Additional presynaptic features necessary for fast synapses is the precise location of Ca^{2+} channels relative to the synaptic release machinery and Ca^{2+} buffers and extrusion mechanisms. As noted above, the duration of the transmitter release process is critically dependent on the spike width. The spike width determines the duration of Ca^{2+} entry, and recent studies show that the Ca^{2+} near the release apparatus decays in less than 1 ms (Bollmann, J. H. and Sakmann, B., 2005). The major wave of Ca^{2+} entry is thought to be controlled by diffusible Ca^{2+} buffers, and indeed during postnatal weeks 2–4 in rats, there is a sharp increase in expression of the buffers calretinin and parvalbumin in the calyces of Held (Felmy, F. and Schneggenburger, R., 2004). Interestingly, the narrower spike-evoked Ca^{2+} profile observed in more mature calyces is insufficient to drive release from younger calyces. By correlating the amount of release with the amount of Ca^{2+} entry, Fedchyshyn M. J. and Wang L. Y. (2005) argued that the degree of cooperativity in Ca^{2+} action at the release site is lower in mature animals. They explain this by saying that Ca^{2+} channels are closer to the releasable vesicles and so that fewer channels are needed to trigger exocytosis. Thus, with maturation the nerve terminal is modified to release a large number of vesicles over a very narrow time period. Synaptic relays are therefore optimized presynaptically for both power and precision.

3.33.8 Reliability of Timing

Reliability can be viewed not only as the likelihood of driving the postsynaptic cell to spike threshold but in terms of temporal precision. When an action potential reaches the presynaptic terminal there is a small delay before the postsynaptic response ensues. This latency, termed the synaptic delay, lasts about 0.3 ms in mature synapses (Guinan, J. J., Jr. and Li, R. Y., 1990; Taschenberger, H. and von Gersdorff, H., 2000) and is extremely reproducible, that is to say it exhibits little trial to trial jitter (Borst, J. G. and Sakmann, B., 1996; Sahara, Y. and Takahashi, T., 2001). Indeed, at mature endbulbs, the standard deviation of jitter in transmission, including the triggering of the action potential, is only 20 μs (Brenowitz, S. and Trussell, L. O., 2001). Thus, even though action potentials themselves may be several hundred microseconds in duration (Brenowitz, S and Trussell, L. O., 2001; Taschenberger, H. and von Gersdorff, H., 2000), the giant synapses have the ability to transmit with much greater precision.

3.33.9 Synaptic Depression

When endbulb or calyceal synapses are activated at high frequencies (>20 Hz), the peak amplitudes of the resulting synaptic currents decline to a steady level over 5–10 stimuli, a process termed synaptic depression. Synaptic depression has been intensively studied in giant synapses because their large size affords the opportunity to work out the pre- and postsynaptic mechanisms of this ubiquitous synaptic feature.

Depression has two sources. In prehearing rodents or embryonic chicks, the transmitter glutamate is not effectively cleared from the synapses and AMPA receptors desensitize (Trussell, L. O. *et al.*, 1993; Otis, T. *et al.*, 1996; Scheuss, V. *et al.*, 2002; Wong, A. Y. *et al.*, 2003). This poor clearance is probably a result of both the immature, sheet-like structure of the synapses and the high probability of exocytosis at neighboring release sites (Kandler, K. and Friauf, E., 1993; Taschenberger, H. *et al.*, 2002). Because glutamate uptake sites reside generally on glial cells (e.g., Turecek, R. and Trussell, L. O., 2000), these factors together lead to pooling and delayed clearance of glutamate. However, in older animals, transmitter release probability declines, the synapses become more fenestrated, and desensitization is minimized (Kandler, K. and Friauf, E., 1993; Brenowitz, S. and Trussell, L. O., 2001; Taschenberger, H. *et al.*, 2002).

The second, and more common, source of depression is a use-dependent reduction in transmitter release. Two views exist as to the basis of presynaptic depression. Depletion of vesicles that are immediately available for exocytosis is reported to account for the majority of depression, even outweighing postsynaptic factors (Schneggenburger, R. *et al.*, 1999; Scheuss, V. *et al.*, 2002). By voltage clamping the presynaptic terminals, one can deliver strong voltage pulses that result in depletion of the readily releasable pool of vesicles. This pool can also be depleted by repetitive presynaptic action potentials. These studies showed that synaptic depression is associated with a significant depletion of the readily releasable pool of vesicles. Moreover, it was apparent that not all vesicles are the same in terms of their likelihood of depletion or their ability to build up again (Sakaba, T. and Neher, E., 2001). One population released quickly but recovered slowly while another had the opposite characteristics. These populations may consists of vesicles with either different distances to Ca^{2+} channels (Wadel, K. *et al.*, 2007) or different sensitivities to Ca^{2+} (Wolfel, M. *et al.*, 2007).

Another view of presynaptic depression at giant auditory synapses is that the probability of release is reduced for docked vesicles, rather than (or in addition to) vesicle depletion. Wu L. G. and Borst J. G. (1999) showed in the calyx of Held that the fraction of the total releasable pool of vesicles that are released by a spike-like stimulus is reduced after a strong, depressing presynaptic voltage step. In endbulbs of Held, where such presynaptic recordings are rare, there is also some evidence for a nondepletion mechanism at work. Bellingham M. C. and Walmsley B. (1999) demonstrated a phase of depression that was Ca^{2+} dependent but apparently not due to depletion, and suggested that Ca^{2+} triggers an event inhibitory to exocytosis. Finally, one component of depression, restricted to lower-frequency responses, is produced by the inactivation of Ca^{2+} currents (Xu, J. and Wu, L. G., 2005). Although this inactivation is rather small for a brief spike-evoked Ca^{2+} current (~10% change), the high degree of cooperativity for Ca^{2+} needed for release means that small changes in the current has a large effect of transmitter output.

As noted above, postsynaptic depression declines with synaptic maturation. While presynaptic depression remains prominent, it also declines in magnitude in the first 2–3 weeks after birth in rodents, but

apparently does not disappear. One reason for this decline is that during the period that the synapse grows, and the number of synaptic release sites increases, the probability of release for each vesicle declines (Brenowitz, S. and Trussell, L. O., 2001; Iwasaki, S. and Takahashi, I., 2001; Taschenberger, H. *et al.*, 2002). In this way, effective transmission is maintained while the likelihood of vesicle depletion diminishes. Thus, several developmental processes converge to improve the ability of giant synapses to sustain release at high frequencies. Despite the continued presence of depression, sufficient numbers of vesicles are released with each impulse that EPSPs are well above spike threshold. Interestingly, depression has been shown to have a physiological role in improvement of coincidence detection in the chick NL. There, frequency-dependent depression of EPSPs ensures that a critical number of coincident events are required for summation, regardless of the frequency of inputs (Kuba, H. *et al.*, 2002; Cook, D. L. *et al.*, 2003).

3.33.10 Alpha-Amino-3-Hydroxy-5-Methyl-4-Isoxazolepropionic Acid Receptors and K^+ Channels

Postsynaptically, the auditory synapse has several physiological properties that allow it to respond to the released glutamate reliably, with negligible delay, and to recover from the response quickly. These include specializations in glutamate receptors and potassium channels (Trussell, L. O., 1999b). As noted above, glutamate activates two main subtypes of ionotropic receptors, the AMPA and NMDA receptors. NMDA receptors, although essential for transmission in many other brain regions, play a minor role in auditory relays. Indeed these receptors show a striking developmental downregulation, so that by the onset of hearing they contribute little to postsynaptic depolarization (Bellingham, M. C. *et al.*, 1998; Taschenberger, H. and von Gersdorff, H., 2000; Iwasaki, S. and Takahashi,T., 2001; Lu, T. and Trussell, L., 2007). AMPA receptors, therefore, mediate almost all excitation at these synapses. EPSCs in auditory relays have a remarkably faster time course than at other CNS synapses. For example, spike-evoked EPSCs in the chick NM rise and decay with a timecourse of around 200 μs (Zhang, S. and Trussell, L. O., 1994b; Brenowitz, S. and Trussell, L. O., 2001). By contrast, EPSCs mediated by AMPA receptors in cortical pyramidal neurons decay in at least 2 ms (Hausser, M. and Roth, A., 1997). The basis for these differences lies in the fact that the AMPA receptors are structurally and functionally different in these two regions. This was initially explored by excising membrane patches from bushy cells and rapidly applying glutamate, which resulted in ionic currents with time courses several fold faster in than glutamate responses in nonauditory neurons (Raman, I. M. *et al.*, 1994). Currents like these were also observed in experiments in which AMPA receptor complimentary DNA (cDNA) was expressed in a heterologous expression system. Specifically, the flop alternative splice variants of the GluR3 or 4 subunits produced currents almost indistinguishable from those of chick or mouse bushy cells (Mosbacher, J. *et al.*, 1994). Similar currents were also obtained from several other auditory cell types, and all of these were shown to express this molecular subtype of AMPA receptor (Gardner, S. M. *et al.*, 2001; Koike-Tani, M. *et al.*, 2005). These results have led to the idea that cells contacted by the auditory nerve, as well as some cell types downstream of the cochlear nucleus, have a particular pattern of gene expression leading to production of a fast auditory AMPA receptor.

The presence of GluR3/4 flop subunits in the AMPA receptors heteromeric complex gives these receptors their characteristic speed. The absence of other subunits also has some meaning for auditory function. The GluR1 subunit is associated with synapses exhibiting use-dependent, long-term potentiation of the EPSP, and the absence of these subunits suggests that many auditory synapses are not plastic (Wang, Y. X. *et al.*, 1998b; Petralia, R. S. *et al.*, 2000). The GluR2 subunit is associated with a reduced Ca^{2+} permeability and enhanced receptor channel conductance (Dingledine, R. *et al.*, 1999), and is poorly expressed in neurons of the cochlear nucleus (Otis, T. S. *et al.*, 1995; Wang, L. Y. *et al.*, 1998b; Gardner, S. M. *et al.*, 1999; Petralia, R. S. *et al.*, 2000; Gardner, S. M. *et al.*, 2001). Accordingly, many cells of the cochlear nucleus express AMPA receptors which allow Ca^{2+} entry with each synaptic response (Otis, T. S. *et al.*, 1995; Gardner, S. M. *et al.*, 1999; Gardner, S. M. *et al.*, 2001); it should not be surprising then that these neurons also express high levels of Ca^{2+} binding proteins (Lohmann, C. and Friauf, E. 1996; Hack, N. J. *et al.*, 2000). The physiological function of this Ca^{2+} is not known. However, the elevated channel conductance may serve a specific role in some cases, to ensure a large synaptic response. mEPSCs are the response to single vesicles of glutamate, and synapses with larger mEPSCs will

produce a larger spike-evoked EPSPs. Comparison of mEPSC among different CNS neurons indicates that bushy cells, contacted by endbulbs of Held, have some of the largest in the brain (Trussell, L. O., 1999a). Interestingly, MNTB neurons have rather normal sized mEPSCs. Perhaps the larger size of the calyx, as compared to the endbulb, obviates the need to enhance mEPSC amplitude.

The second factor promoting rapid relay of synaptic signals is the intrinsic properties of the postsynaptic cell, generally determined by the complement of K^+ channels. This aspect of the physiology is covered by Paul Manis in this series, and so will only be addressed briefly. Neurons of avian NM and NL cells, as well as mammalian bushy, octopus and MSO cells, express several major voltage-gated currents. Two of these are most notable here, a low-voltage-activated K^+ current (LVA), blockable with dendrotoxin, and a high-voltage-activated current (HVA) blocked by tetraethylammonium (TEA) (Trussell, L. O., 1999b). The latter is the major outward current repolarizing the action potential. The former plays a very different role: once the cell becomes slightly depolarized above rest, this current activates and effectively raises spike threshold. Because of this, the cell can only spike if it can reach threshold before the current activates. After the spike, the cell must return back to rest to be able to spike again; thus synaptic currents must be brief to allow rapid firing. Blockade of the HVA in bushy or MNTB cells broadens the spike (Zhang, S. and Trussell, L. O., 1994a; Wang, L. Y. *et al.*, 1998a), while block of LVA promotes repetitive firing (Brew, H. M. and Forsythe, I. D., 1995; Rathouz, M. and Trussell, L., 1998; Wang, L. Y. *et al.*, 1998a). Thus, the LVA helps maintain a single postsynaptic spike for a single presynaptic spike (Brew, H. M. and Forsythe, I. D., 1995). The effect of the LVA on spike threshold is probably essential to the detection of coincidence of synaptic inputs. Because the LVA turns on quickly, subthreshold EPSPs produced by convergent inputs must all occur within a narrow time window to allow summation to threshold (Ferragamo, M. J. and Oertel, D., 2002).

3.33.11 Determination of Synaptic Information Transfer

Auditory nerve fibers innervate diverse cell types each with very specific processing roles. What are the common physiological elements at these synapses? We have seen that synapses of the auditory nerve use glutamate receptors with rapid kinetics; however, this is not always the case. Synapses and AMPA receptors on basal dendrites of fusiform cells of the DCN exhibit much slower kinetics than synapses in the VCN or synapses onto interneurons in the DCN (Gardner, S. M. *et al.*, 1999; Gardner, S. M. *et al.*, 2001). Fusiform cells also receive glutamatergic contacts of granule cells on their apical dendrites, and these synapses also have slow kinetics. Thus, it may be that the fast synaptic phenotype is restricted to cells whose primary excitatory input is the auditory nerve. Interestingly, although synapses on both apical and basal dendrites are slower than VCN synapses, they employ different receptor subunits, which are differentially targeted to the two dendrites (Rubio, M. E. and Wenthold, R. J., 1999), suggesting very local control of synaptic properties.

Even among these auditory nerve-dominant neurons, synaptic function may vary. In birds, auditory nerve fibers terminate in two cochlear nuclei, the NM and the nucleus angularis, the latter being involved in sound localization using intensity cues (Takahashi, T. *et al.*, 1984). Fast AMPA receptors appear to mediate transmission in both nuclei (Raman, I. M. *et al.*, 1994; MacLeod, K. M. and Carr, C. E., 2005b), despite their neurons having very different membrane firing properties (Soares, D. *et al.*, 2002; Fukui, I. and Ohmori, H., 2003; Zhang, S. and Trussell, L. O, 1994a). Moreover, EPSPs in nucleus angularis are slower than in NM, due to their different postsynaptic membrane properties, and do not exhibit the acute presynaptic synaptic depression seen in calyceal synapses (MacLeod, K. M. and Carr, C. E., 2005a; 2005b). These features are ideal for promoting integration of EPSPs generated by multiple auditory nerve fibers in nucleus angularis. Thus, both pre- and postsynaptic physiology may vary in a cell-type-specific manner despite a common presynaptic source of input. This is reminiscent of the varying synaptic properties among different neocortical excitatory synapses (Markram, H. *et al.*, 1998), and suggests that synaptic properties are determined not just by the identity of the pre- or postsynaptic cell but in a synapse-specific manner.

3.33.12 Endbulbs versus Calyces versus Hair Cells

Up to this point we have treated endbulbs and calyces of Held as being equivalent in their physiological properties, on the assumption that relays are

relays. However, the differences between these synapses may give insight into their respective roles. Endbulbs are smaller synapses, which concentrate as much transmission power as a calyx into a smaller space. Because each bushy cells received several axonal inputs, some synaptic integration is possible. Indeed, Xu-Friedman M. and Regehr W. (2005) have shown that even though these inputs are suprathreshold, the degree of jitter in firing of presynaptic inputs can be reduced in the output of the bushy cell. Say that three input fibers fire with some jitter around the phase of the sound stimulus. The first EPSP will trigger a spike and therefore the average timing of the output spikes will be concentrated and shifted slightly earlier in phase. Each calyx, by contrast, is the sole excitatory drive for the MNTB principle cell. These synaptic features, as well as the very large size of the presynaptic axon, suggest that the synaptic adaptations of the calyx are geared for reliability and minimizing transmission delays, rather than preservation or improvement in phase locking.

Because all precise auditory signaling arises from the hair cell synapse, it is of interest to compare the functioning of this synapse to that of its downstream partners in the CNS.

As described in the chapter by William Roberts, hair cells utilize a very different synaptic structure; accordingly, they encode neural information through a different cellular algorithm. Each auditory nerve fiber is driven by a single synaptic release site, called a ribbon synapse, which is suited for graded, rather than spike-triggered, transmission (Fuchs, P. A., 2005). Because the postsynaptic fiber is excited following exocytosis from a single release site, involving one or a few vesicles (Crawford, A. C. and Fettiplace, R., 1980; Siegel, J. H., 1992), the number of vesicles released per cycle of sound contains little information. Rather, what seems to matter at this synapse is the phase-locked rise in probability of release at each cycle for low-frequency sounds (<2 kHz) or the average number of randomized releases for higher-frequency sound. Unlike CNS synapses, in which higher-frequency presynaptic firing reflects higher intensity sounds, sound intensity in the hair cell is encoded by the amplitude of membrane depolarization (Palmer, A. R. and Russell, I. J., 1986). At the level of the hair cell synapse, this higher depolarization should increase the frequency of exocytic events and thus the frequency of spikes in the nerve fiber.

At the other end of the auditory nerve fiber, single release sites contribute only slightly to raising the postsynaptic cell to threshold, and so find strength in numbers; postsynaptic excitation requires either endbulb synapses or many convergent fibers. These nerve terminals are only excited by all-or-nothing spikes. Although such transmission is not graded, release is very sensitive to variation in spike width (Borst, J. G. and Sakmann, B., 1999; Bollmann, J. H. and Sakmann, B., 2005); this variation eventually may be shown to be an essential means for regulation of transmission in auditory synapses.

3.33.13 Comparison to Other Fast Synapses

How special are auditory timing synapses compared to others in the CNS? Certainly the jitter in postsynaptic spike timing is greater in cortical and hippocampal neurons, even for those that are considered to provide well-timed signaling. We have already seen that AMPA receptor kinetics are several times slower in most nonauditory brain regions. On the other hand, some of the specializations we have described are found in a few brain regions that are not associated with such precise temporal fidelity. For example, the fast-gating AMPA receptors that are characteristic of auditory nerve targets mediate transmission in retinal horizontal cells, even though glutamate is released onto them much more asynchronously than in fast, phasic synapses (Eliasof, S. and Jahr, C. E., 1997). EPSCs almost as fast as auditory EPSCs are also found in cerebellar stellate cells (Carter, A. G. and Regehr, W. G., 2002). Cerebellar granule cells feature EPSCs whose timing of multi-vesicular glutamate release from mossy fibers is extremely precise, with a temporal dispersion in release of less than 100 μs (Sargent, P. B. *et al.*, 2005). However, unlike auditory relays, these synapses also show considerable trial-to-trial fluctuation in strength. Thus, precisely timed or fast EPSCs has been selected for in several other brain regions, but it remains unclear what function it serves there.

3.33.14 Control of Fast Auditory Signaling

3.33.14.1 Inhibition

Auditory relay neurons and coincidence detectors all receive substantial inhibitory input from interneurons or from cells in nearby nuclei. Glyinergic inputs

on mammalian bushy cells of the VCN, which probably originate from subtypes of stellate cell within the VCN and from tuberculoventral cells of the DCN, may regulate multiple aspects of acoustic responses (Wickesberg, R. E. and Oertel, D., 1990; Backoff, P. M. *et al.*, 1997; Ferragamo, M. J. *et al.*, 1998; Kopp-Scheinpflug, C. *et al.*, 2002). MNTB receives very powerful glycinergic inputs (Banks, M. I. and Smith, P. H., 1992; Awatramani, G. B. *et al.*, 2004), possibly originating from MNTB collaterals or from neighboring olivary nuclei (Kuwabara, N. *et al.*, 1991). Avian cochlear nuclei and NL receive GABAergic input from the superior olivary nucleus (Burger, R. M. *et al.*, 2005). MNTB provides fast inhibition to LSO and probably also to MSO (Kuwabara, N. and Zook, J. M., 1991; Banks, M. I. and Smith, P. H., 1992; Kuwabara, N. and Zook, J. M., 1992; Wu, S. H. and Kelly, J. B., 1992; Kim, G. and Kandler, K., 2003). Birds and mammals employ strikingly different mechanisms for mediating inhibition of synaptic relays. Here we will focus on the rat MNTB and the chick NM to contrast these very different inhibitory systems.

Glycine serves as the major inhibitory transmitter of the lower auditory pathways, and elicits fast, hyperpolarizing synaptic potentials. In the MNTB, these inhibitory postsynaptic potentials (IPSPs) are driven by very large conductance and fast kinetic synaptic responses, which are blocked by the glycine receptor antagonists strychnine (Banks, M. I. and Smith, P. H., 1992; Awatramani, G. B. *et al.*, 2004; 2005b). In mature rats, the size of the synaptic conductance is almost as great as that of the calyceal EPSC (Awatramani, G. B. *et al.*, 2004). Moreover, the currents are quite brief, with decay times of evoked responses less than 2 ms, and quantal currents of less than 1 ms at physiological temperature (Awatramani, G. B. *et al.*, 2004). The IPSCs are in fact the fastest glycine synaptic events that have been observed, suggesting the possibility that, like the AMPA receptor, the auditory system has employed a receptor modification to gain fast signaling properties. The size and speed of the IPSCs are well suited for abbreviating a train of calyceal-evoked EPSPs, and could therefore play a role in rapidly sculpting the response to a complex acoustic stimulus. Indeed, one recent study observed two-tone suppression in the MNTB that appeared to arise by a postsynaptic mechanism, as one might expect of inhibition triggered in response to frequencies near an MNTB neuron's characteristic frequency (Kopp-Scheinpflug, C. *et al.*, 2003). It will be essential to determine the source of this inhibition and how it is activated *in vivo* in order to develop more testable hypotheses about the role of inhibition.

By contrast, inhibition in avian auditory brainstem is mediated by GABA (Yang, L. *et al.*, 1999; Monsivais, P. *et al.*, 2000). Both the kinetics and ionic driving force of the GABAergic synaptic responses are geared for tonic inhibition through prolonged depolarization of the postsynaptic cell, rather than abrupt well-timed hyperpolarization as in mammals (Lu, T. and Trussell, L. O., 2000; Lu, T. and Trussell, L. O., 2001). GABAergic synaptic currents have a decay time over 10 times slower than the glycinergic currents. Moreover, when stimulated in high-frequency trains, the GABA release becomes desynchronized from the timing of the presynaptic spikes, thus generating a tonic GABAergic current (Lu, T. and Trussell, L. O., 2000). Remarkably, the reversal potential for GABA is far above spike threshold, between −36 and −25 mV in neurons of NM, due to an elevated intracellular Cl^- concentration (Lu, T. and Trussell, L. O., 2001; Monsivais, P. and Rubel, E. W., 2001). Although some IPSPs can trigger spikes at their onset, their tonic activation keeps the neuron depolarized; by activating K^+ currents and inactivating Na^+ currents, spike threshold is raised and excitation quickly ceases. Given the physiology and circuitry of inhibition, it has been proposed that GABAergic transmission serves to offset the effects of interaural level differences in auditory timing pathways (Burger, R. M. *et al.*, 2005). Thus, in mammals and birds, decidedly different modes of inhibition are employed, despite the remarkable similar mechanisms for fast excitation using calyces, fast glutamate receptors, and a complement of high- and low-threshold K^+ channels.

3.33.14.2 Presynaptic Modulation

Endbulbs and calyces are endowed with a variety of presynaptic mechanisms for modulation of transmitter release, besides the use-dependent synaptic depression described above (Trussell, L. O., 2002). Most work has focused on the calyx of Held, because its large size enables direct evaluation of the presynaptic effects of modulatory agents. These agents act on presynaptic receptors for norepinephrine, GABA (two receptor types), glycine, adenosine, glutamate (two types), and endocannabinoids (Takahashi, T. *et al.*, 1996; Brenowitz, S. *et al.*, 1998; Takahashi, T. *et al.*, 1998; Turecek, R. and Trussell, L. O., 2001;

Leao, R. M. and von Gersdorff. H., 2002; Turecek, R. and Trussell, L. O., 2002; Kimura, M. *et al.*, 2003; Sakaba, T. and Neher, E., 2003; Kushmerick, C. *et al.*, 2004; Takago, H. *et al.*, 2005). Two major schemes have been described for how these receptors work. Activation of presynaptic G-protein-coupled receptors inhibit Ca^{2+} channels and thus reduce the Ca^{2+} signal needed to trigger exocytosis (Takahashi, T. *et al.*, 1998; Kajikawa, Y. *et al.*, 2001). On the other hand, activation of ionotropic receptors depolarize the terminal, weakly activate Ca^{2+} channels, and induce a facilitation of glutamate release (Turecek, R. and Trussell, L. O., 2001; Awatramani, G. B. *et al.*, 2005a). In addition to effects on baseline synaptic strength, these receptors can also alter how quickly the synapse can recover from a period of synaptic depression. GABA, acting via a G-protein-coupled receptor, reduces cAMP levels in the synapse and slows the replenishment of vesicle pools after synaptic depression (Sakaba, T. and Neher, E., 2003). By contrast, glutamate, acting on group III metabotropic receptors, accelerates recovery from depression (Billups, B. *et al.*, 2005). Thus, calyces are endowed with a multitude of presynaptic receptor subtypes, which regulate glutamate release through many signaling pathways.

What are the physiological roles of these presynaptic receptors? Remarkably, only two studies have shown activation of such receptors by synaptically released transmitter. Synaptically released glutamate reaches presynaptic group III receptors (von Gersdorff, H. *et al.*, 1997; Billups, B. *et al.*, 2005), while activation of glycinergic inputs to MNTB principle cells releases sufficient glycine to modulate calyceal function (Turecek, R. and Trussell, L. O., 2001). For the other modulators, a physiological role is obscure, in part because the sources of endogenous transmitters is not known. It is of interest that some of these receptors, such as noradrenergic and metabotropic receptors, are downregulated during development. It may be that young synapses simply express many types of receptor, and these are pared down according to the needs of the mature functioning system. Alternatively, such mechanisms may act *in vivo*, but under conditions that have not yet been replicated in the brain slice studies. An important area for future research will be to identify how these various receptors are activated by endogenous transmitters and how such activation modifies the relay function of giant auditory synapses.

Glossary

inbred strain Mice of an inbred strain are genetically identical to one another and homozygous at all genetic loci.

sound pressure level (SPL) Decibels re: 20 μPa

3.34.1 Introduction

The acoustic startle response (ASR) provides an important behavioral tool for assessing properties of the auditory system, as discussed below. More importantly, however, the ASR is a phenomenon having relevance for a wide variety of issues important in the study of sensory systems. Whereas the ASR is by definition a behavior, it is more importantly a sensorimotor reflex and as such cannot be divorced from the auditory processes that trigger it. We can conceptualize the ASR as a sensorimotor system for which the behavioral component is linked to certain aspects of the acoustic stimuli that evoke the response and to events that surround it in space and time. The adequate stimuli for activating the system are intense sounds with an abrupt onset that are unexpected and/or not monotonous (Fleshler, M., 1965; Willott, J. F. *et al.*, 1979; Ison, J. R., 2001). Arguably, the sensory, central modulatory, and motor circuits that comprise the ASR system can be viewed as a sensory filter or detector of these features. The ASR may be influenced by location, spectral

content, and other qualities, but these properties are not critical for activation of the system. Importantly, activation of this sensorimotor system is strongly modified by emotional states, temporally proximal events, and ambient stimulus conditions, as discussed below.

3.34.2 The Acoustic Startle Response as a Research Tool

The ASR has enjoyed wide use as a tool in auditory and other research, and there are good reasons for its popularity. The ASR:

- is a fundamental auditory behavior, occurring widely in mammals, including humans (Landis, C. and Hunt, W., 1939; Davis, M., 1984; Ison, J. R., 2001) and has been well studied in the latter species (Dawson, M. E. *et al.*, 1999);
- is simple enough to be accurately isolated and measured;
- is an interesting and important auditory behavior in its own right;
- can be used as a measure of behavioral responsiveness to intense or unexpected sounds;
- serves as a behavioral probe to evaluate responses to environmental conditions, emotional situations, neurobehavioral disorders, strain differences, or drugs (e.g., Hoffman, H. S. and Ison, J. R., 1980; Braff, D. *et al.*, 1992; Glowa, J. R. and Hansen, C. T., 1994; Falls, W. A. *et al.*, 1997a; 1997b; Geyer, M. A., 1998; Kline, L. *et al.*, 1998; Zhang, J. *et al.*, 2000; Ison, J. R., 2001);
- can be used as a measure of auditory processing in neurobehaviorally normal populations (Reiter, L. A. and Ison, J. R., 1979; Young, J. S. and Fechter, L. D., 1983; Carlson, S. and Willott, J. F., 1996; Jeskey, J. E. and Willott, J. F., 2000; Willott, J. F. and Turner, J. G., 2000);
- is an auditory behavior for which the neurophysiological and neurochemical mechanisms, neural pathways, and physiology are reasonably well understood;
- is an auditory behavior for which quantitative measurement is relatively simple, fast, and reliable; and
- varies substantially among different genetic strains of mice and/or mutants in order for inheritance mapping and other genetic techniques to be applied.

3.34.3 Properties of the Acoustic Startle Response

3.34.3.1 Description and Measurement of the Behavior

In rats and mice, the ASR is manifested as a transient, crouchlike movement of the body and flinching of the head and pinnae. To measure the response, the animal is typically placed in a movement-sensitive device that produces a voltage that can be recorded. A startle evokes a transient voltage spike within relatively short latency (5–30 ms, depending on the inertia and sensitivity of the device). ASR parameters that are easily measured include the amplitude (e.g., peak voltage of the response) and latency (time elapsed between onset of stimulus and onset of response). Amplitude-intensity functions and startle thresholds can be measured by varying the level of the startle stimuli.

3.34.3.1.1 Suprathreshold performance is not related to threshold in a simple manner

ASRs are elicited by stimulus levels well above the sensory threshold (Willott, J. F. *et al.*, 1979; 1984) and startle amplitude has little if any relationship to threshold unless hearing loss is quite severe (Parham, K. and Willott, J. F., 1988; Carlson, S. and Willott, J. F., 1996). Indeed, some hearing-impaired mice have very large startle responses. For example, mice of the BUB/BnJ inbred strain have very large ASRs (see Figure 1), yet they exhibit substantial threshold elevations (Willott, J. F. *et al.*, 2003).

3.34.3.2 Modulation of the Acoustic Startle Response by History, Environment, Genes, and Other Variables

An extraordinary aspect of the ASR system is the ease by which it is modified by precedent sensory stimuli (prepulse inhibition; PPI), fear (fear-potentiated startle; FPS), monotonous repetition (habituation), continuous background noise, and other variables. Whereas the ASR is sensitive to certain stimulus features mentioned earlier, behavioral manifestation of the ASR system is affected by many variables.

3.34.3.2.1 Prepulse inhibition

PPI reflects the perceptual impact or salience of sensory stimuli and their regulation by the central nervous system. PPI is manifested as follows: an

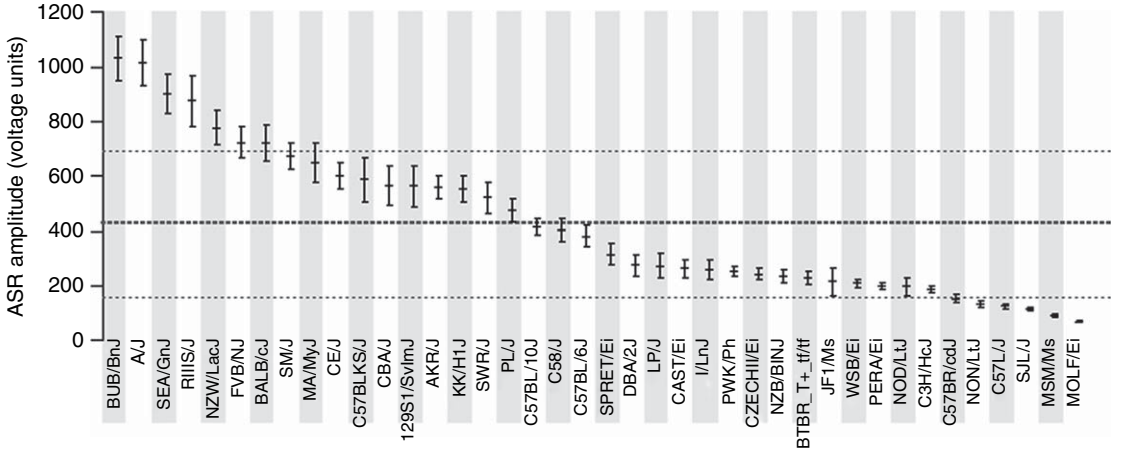

Figure 1 Mean startle amplitudes of 40 inbred strains, males and females combined (in most cases 10 of each per strain), evoked by 100 dB sound pressure level (SPL) noise bursts. Error bars represent standard error of mean for each strain. Bold dashed line, grand mean for all strains. Light dashed lines, ±1 standard deviation of grand mean. Reprinted from Willott, J. F., Tanner, L., O'Steen, J., Johnson, K. R., Bogue, M. A., and Gagnon, L. 2003. Startle and prepulse inhibition in forty inbred strains of mice. Behav. Neurosci. 117, 716-727. Copyright © 2003 by the American Psychological Association, with permission.

audible prepulse stimulus (S1) is presented about 100 ms before an intense startle-eliciting stimulus (S2). Whether the prepulse is a tone burst, a gap in the background noise, or other sensory change, activation of the PPI circuit inhibits the startle pathway for a period lasting several hundred milliseconds, resulting in an inhibited ASR with a reduced amplitude during this interval. PPI can be expressed by the simple ratio of ASR amplitude evoked by S2 when S1 has been presented, to ASR amplitude when S2 has been presented without S1.

3.34.3.2.2 Fear-potentiated startle

FPS is widely used to investigate the neurobiological basis of fear or anxiety. In FPS a subject learns to fear an auditory or visual cue that was paired with footshock; later, when startled in the presence of the cue, startle amplitude is increased as a function of the learned fear. Because FPS utilizes Pavlovian conditioning procedures, it is also used to investigate the neurobiological basis of learning and memory (Davis, M. and Astrachan, D. I., 1978; Miserendino, M. J. D. *et al.*, 1990; Campeau, S. and Davis, M., 1992; Falls, W. A. *et al.*, 1992; Campeau, S. and Davis, M., 1995a; Falls, W. A. *et al.*, 1997b; Gewirtz, J. C. and Davis, M., 1997).

3.34.3.2.3 Sensitization

Sensitization is the phenomenon whereby responsiveness is generally enhanced in a nonspecific (nonassociative) manner, usually by an intense or highly arousing event. The nonassociative aspect differentiates it from FPS, although in both cases ASR amplitude is increased. The ASR can be used as a model to study sensitization involving sensory stimuli (Koch, M., 1999; Plappert, C. F. and Pilz, P. K., 2001).

3.34.3.2.4 Habituation

The ASR exhibits rapid habituation and can be used as a model to study the phenomenon (Thompson, R. F. and Spencer, W. A., 1966; Groves, P. M., *et al.*, 1974; Davis, M., 1984; Koch, M., 1999). Habituation occurs when repeated, monotonous presentation of a startle stimulus results in diminution or cessation of the response, despite the fact that the stimuli are still being processed by the auditory system (i.e., threshold shifts, adaptation, or fatigue have not taken place). A good understanding of, and access to, the startle pathway allows habituation to be studied at many levels. For example, Weber M. *et al.* (2002) explored distinct synapses of the neuronal startle pathway in rat brain slices by patch-clamp recordings neurons in the startle pathway and found that response parameters associated with synaptic depression *in vitro* matched those of ASR habituation *in vivo*.

3.34.3.2.5 Ambient noise

The presence of continuous background noise modulates the ASR system. In general, a relatively low

level of continuous background noise tends to potentiate the ASR whereas high levels tend to suppress the ASR (see Carlson, S. and Willott, J. F., 2001 for a review). It is common for researchers to use a constant background noise during ASR testing, and this runs the risk of unintentionally modulating the ASR up or down.

3.34.3.2.6 Circadian rhythms

The ASR system exhibits circadian modulation, with amplitudes greater at night in nocturnal rats and mice. The changes in ASR amplitude do not appear to be correlated with general motor activity (Horlington, M., 1970) or auditory sensitivity (Chabot, C. C. and Taylor, D. H., 1992). At least one site of circadian modulation appears to occur at the level below the brainstem (Frankland, P. W. and Ralph, M. R., 1995), so it is not clear if the modulation is occurring in the brain.

3.34.3.2.7 Genetics

Because the ASR and PPI have been well studied in mice, a number of studies have used the behaviors as a behavior-genetics tool (e.g., Bullock, A. E. *et al.*, 1997; Logue, S. F. *et al.*, 1997; Paylor, R. and Crawley, J. N., 1997; Hitzemann, R. *et al.*, 2001; Plappert, C. F. and Pilz, P. K., 2001; Ralph, R. J. *et al.*, 2001; Willott, J. F. *et al.*, 2003). Whereas, aspects of these studies are not necessarily aimed at the genetics of hearing or auditory behavior *per se*, they often provide insights. Figure 1 summarizes ASR amplitudes from 40 inbred strains of mice all having similar age and rearing conditions. It is evident that the size of startle varies greatly among strains – presumably as a function of genetic differences. Some of the strains with very large or very small ASRs have similar, normal hearing suggesting that genetic effects on central auditory processes and/or gating is responsible for the differences, rather than cochlear sensitivity.

3.34.3.2.8 Neurotransmitter systems

The ASR system is readily amenable to experiments on neurotransmitter systems and drug effects. For example, drugs affecting central dopamine (DA) systems (especially the mesolimbic system) have been well studied and shown to play an important role in startle (Meloni, E. G. and Davis, M., 2000) and PPI and related paradigms. A number of studies in humans and rodents have shown that overactivity of DA induced by DA agonists or other means results in reduced PPI and reduced gating of evoked potentials (Koch, M. and Hauber, W., 1998; Swerdlow, N. R. *et al.*, 1990; Zhang, J. *et al.*, 2000).

Another example is the role of acetylcholine. Fendt M. and Koch M. (1999) showed that the nucleus reticularis pontis caudalis (PnC) receives an inhibitory cholinergic projection that might be important for PPI.

3.34.3.2.9 Psychological states or pathology

The startle reflex is highly sensitive to various factors that are of interest in the studies of emotional disorders and has promoted new areas of investigations in psychiatry. Alteration of the startle response (by PPI in particular) has been widely used in models of psychiatric conditions (Koch, M., 1999; Grillon, C. and Baas, J., 2003) including schizophrenia (Braff, D. L. and Geyer, M. A., 1990; Geyer, M. A. *et al.*, 1990; Cadenhead, K. S. *et al.*, 1993; Braff, D. L. *et al.*, 1995; Swerdlow, N. R. and Geyer, M. A., 1998), Huntington's disease (Swerdlow, N. R. *et al.*, 1995), posttraumatic stress disorder (Pitman, R. K. *et al.*, 1999), fear and anxiety, affective disturbances, sensitization, and motivational states (Dawson, M. E. *et al.*, 1999). Most notably, schizophrenic patients exhibit deficits in both the PPI of startle and the habituation of startle, and evidence supports involvement of mesolimbic dopaminergic systems in the modulation of PPI or sensorimotor gating and the importance of central serotonergic systems in the habituation of startle (Geyer, M. A. *et al.*, 1990). Whereas these studies have tended to focus on gating mechanisms, alterations in central auditory processing may also be involved, and this topic deserves additional attention (Willott, J. F. *et al.*, 2003).

3.34.3.2.10 Relationship between hearing loss and central plasticity

High-frequency hearing loss results in plasticity of the central auditory system, whereby audible lower frequencies become more strongly represented in the inferior colliculus (IC) and elsewhere (Willott, J. F., 1996). This plasticity is accompanied by parallel changes in the strength of PPI (Willott, J. F. *et al.*, 1994; Carlson, S. and Willott, J. F., 1996; Willott, J. F. and Turner, J. G., 2000). As high-frequency S1s become ineffective, lower-frequency S1s become more salient, producing stronger PPI.

3.34.4 Anatomical Pathways

3.34.4.1 The Acoustic Startle Response Pathway

The primary neural pathway for the ASR resides in the lower brainstem, with auditory neurons in the cochlear nucleus and/or cochlear nerve root projecting to startle-triggering neurons of the reticular formation. The most basic acoustic startle pathway is supported by only a few synaptic relays: auditory nerve ⇒ ventral cochlear nucleus (VCN) ⇒ giant neurons of the PnC ⇒ spinal cord and motor neurons ⇒ muscles (Davis, M. *et al.*, 1982; Huffman, R. F. and Henson, O. W., 1990; Kandler, K. and Herbert, H., 1991; Lingenhöhl, K. and Friauf, E., 1994; Lee, Y. *et al.*, 1996; Yeomans, J. S. and Frankland, P. W., 1996; Koch, M., 1999; Scott, B. W. *et al.*, 1999; Swerdlow, N. R. and Geyer, M. A., 1999; Weber, M. *et al.*, 2002). The PnC, whose axons descend the spinal cord is especially important. Koch M. and Schnitzler H. U. (1997) noted the PnC is also the target of input from various brain nuclei which are involved in modulation of the ASR (e.g., PPI, FPS, sensitization, habituation). Hence, the PnC can be described as a sensorimotor interface, where the transition of sensory input into the motor output can be directly influenced by excitatory or inhibitory afferents.

3.34.4.2 The Prepulse Inhibition Pathway

PPI results from modulation of the startle pathway by circuit(s) that include prepulse-activated auditory nuclei, with efferents from the IC playing an especially important role (Parham, K. and Willott, J. F., 1990; Carlson, S. and Willott, J. F., 1996; Li, L. *et al.*, 1998a; 1998b). Neural output from the central auditory system activates other postauditory components of the PPI neural circuitry, including pathways that ultimately descend to the PnC and inhibit the giant neurons that trigger the startle reflex (e.g., Hoffman, H. S. and Ison, J. R., 1980; Davis, M., 1984; Willott, J. F. *et al.*, 1994; Carlson, S. and Willott, J. F., 1998; Li, L. *et al.*, 1998b; Koch, M., 1999; Ison, J. R., 2001).

3.34.4.3 Other Modulating Pathways

A number of brain structures appear capable of modulating the ASR and/or PPI neural circuitry. Anatomical and lesion-behavior studies have indicated that auditory cortex, IC, and substantia nigra pars reticulata project to the startle circuitry and may provide tonic inhibition and/or modulation of the ASR (Parham, K. and Willott, J. F., 1990; Hunter, K. P. and Willott, J. F., 1993; Koch, M. *et al.*, 2000; Leaton, R. N. and Brucato, F. H., 2001). In various neurobehavioral conditions associated with impaired PPI or startle (see Section 3.34.3.2.9), brain regions such as the limbic cortex, ventral striatum, pallidum, and pedunculopontine nucleus have been implicated (Koch, M., 1999; Swerdlow, N. R. and Geyer, M. A., 1999). Finally, a key structure of the FPS pathway is the amygdala, which receives information from the auditory system via the auditory thalamus and cortex and projects to the startle circuit (e.g., Rosen, J. B. *et al.*, 1991; Romanski, L. M. and LeDoux, J. E., 1992; Campeau, S. and Davis, M., 1995a; 1995b; Falls, W. A. *et al.*, 1997a; Leaton, R. N., 2003).

3.34.5 Auditory Neurophysiology

Carlson S. and Willott J. F. (1998) studied single-unit responses of PnC neurons that presumably trigger the ASR in mice. They performed the study in the fashion of a typical auditory single-unit study: stimuli were presented and the extracellular responses elicited were recorded and described. Responses of PnC neurons generally paralleled those of the ASR (see also Wu, M. F. *et al.*, 1988; Lingenhöhl, K. and Friauf, E., 1992; 1994). In order to evoke auditory responses in these neurons, stimuli had to be intense (e.g., about 100 dB sound pressure level (SPL)), have an abrupt onset, and be repeated at a relatively slow rate. The responses of most PnC neurons were transient – one or a few responses occurred shortly after the onset of the sound. The latency of these onset responses were short enough (as short as 4 ms) to trigger the ASR behavior. PnC neurons exhibited little or no spontaneous activity. PnC neurons responded to a startle stimulus when it was repeated at a slow rate of one every 10 s, as shown in Figure 2 ($0.1\,s^{-1}$; filled circles). By contrast, when the stimulus was presented at a rate of $1\,s^{-1}$ (unfilled circles) the evoked discharges quickly waned, as does the ASR. Stimuli with moderate intensities (e.g., 70 dB SPL) – well above the absolute threshold of hearing but ineffective startle stimuli – excited PnC neurons weakly, if at all. However, when a 70 dB tone was presented 100 ms before an effective (100 dB) startle stimulus the responses to the startle stimulus was inhibited – that is, PPI was exhibited a the neuronal level. Figure 3 presents examples of such responses; when the startle

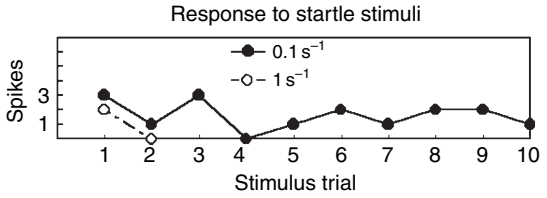

Figure 2 Effects of stimulus presentation rate on responses of a nucleus reticularis pontis caudalis neuron to a series of 10 startle stimuli (100 dB sound pressure level noise bursts). At a rate of 1 s^{-1} (unfilled circles, dashed lines), two action potentials were evoked by the first stimulus, but thereafter, subsequent stimuli no longer elicited responses. By contrast, presentation of the startle stimulus at a slower rate of 0.1 s^{-1} (filled circles, unbroken line) continued to elicit action potentials for most stimuli. Reproduced from Carlson, S. and Willott, J. F. 1998. Caudal pontine reticular formation of C57BL/6J mice: responses to startle stimuli, inhibition by tones, plasticity. J. Neurophysiol. 79, 2603–2614, use with permission from the American Physiological Society.

stimulus (S2) was preceded by a prepulse (S1), few spikes were evoked (filled squares) compared to those evoked by S2 alone (unfilled squares).

3.34.6 Function and Adaptive Significance

Sensory systems evolved to trigger, guide, direct, or modulate behaviors. The fundamental nature of the startle – retraction/withdrawal of head and body – suggests a protective role from sudden, potentially injurious events. Yeomans J. S. *et al.* (2002) noted that intense tactile, acoustic, or vestibular stimuli activate their respective cranial nerves and primary sensory nuclei which all project to PnC giant neurons critical for the startle reflex. Cross-modal summation of this input to the PnC is strong, suggesting convergence of modalities in startle. This summation declines sharply if the cross-modal stimuli are not synchronous. Head impact stimuli activate trigeminal, acoustic, and vestibular systems together, suggesting that the startle response protects the body from impact stimuli.

There are, however, issues that do not fit nicely with the notion that the ASR has adaptive value. For example, an ASR might be evoked by predator movement, giving away prey position, a seemingly maladaptive response. Moreover, some species (e.g., rabbits and chinchillas) do not readily exhibit ASRs suggesting that prey species can be successful

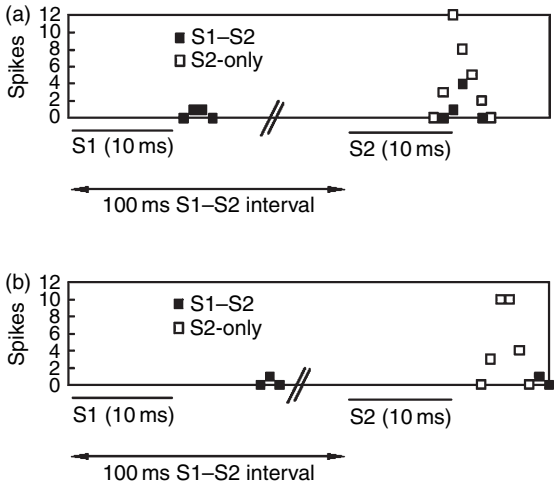

Figure 3 Action potentials in nucleus reticularis pontis caudalis neurons evoked by S1–S2 pairs and by S2 alone. Poststimulus time histograms show extracellularly recorded action potentials in response to a 100 dB sound pressure level (SPL) startle stimuli (S2, horizontal line under right portion of the panel) and to a 70 dB SPL 10 ms tone (horizontal line under left portion of panel) paired with S2. The number of action potentials when S2 was presented alone is indicated by unfilled squares; the number of action potentials evoked by both S1 and S2 (when S2 was preceded by S1) is indicated by filled squares. In each case, 10 stimuli or stimulus pairs were presented at a rate of one per 10 s and the total number of action potentials at each 1 ms time bin was summed. In example (a), S2, when not preceded by S1, evoked almost 30 action potentials for 10 stimulus presentations. When a 4 kHz tone S1 preceded S2, the number of action potentials evoked by S2 was reduced (a few responses were also evoked by S1). In (b), S1 did not evoke any action potentials (left portion of panel) but caused a substantial reduction in action potentials evoked by S2 (right portion of panel). Reproduced from Carlson, S., and Willott, J. F. 1998. Caudal pontine reticular formation of C57BL/6J mice: responses to startle stimuli, inhibition by tones, plasticity. J. Neurophysiol. 79, 2603–2614, used with permission from the American Physiological Society.

without startle. Perhaps the ASR has minimal survival value but is an epiphenomenon – an escape response that is initiated by a sudden event, then aborted by inhibition as the nervous system determines that escape is unwarranted or detrimental; by this time, however a burst of movement has already occurred.

Glossary

avian Of or pertaining to birds.

azimuth The angular distance or position in the horizontal plane.

delay line A component of either a model or physical circuit that introduces time delays into a processing unit where time delay is proportional to the length of the component.

dichotic The binaural presentation of stimuli that differ in one or more aspects (i.e., frequency, intensity, etc.).

diotic The binaural presentation of identical stimuli to the two ears.

interaural phase disparity The difference in stimulus phase at the two ears, which varies with interaural time disparity for freefield stimuli.

interaural intensity disparity The difference in stimulus intensity measured at the two ears, the magnitude of which depends on physical features of the listener, such as head size, and stimulus frequency.

interaural time disparity The difference in arrival time for a particular sound stimulus at the two ears, the magnitude of which depends primarily on head size and the speed of sound in the medium.

K^+_{HT} High-threshold potassium conductance through a membrane, usually associated with Kv3 family potassium channels.

K^+_{LVA} Low-threshold potassium conductance through a membrane, usually associated with Kv1 family potassium channels.

3.35.1 Overview and Background

Binaural hearing provides important perceptual information for localizing acoustic information in space and for enhancing signal-to-noise characteristics, especially in noisy environments. Interaural time disparities (ITDs) are the principal cue animals use to localize low-frequency sounds in the azimuthal plane (horizon). In reptiles, birds, and mammals specialized regions in the auditory brainstem are devoted to

processing this cue (Carr, C. E. and Code, R. A., 2000; Carr, C. E. and Soares, D., 2002). These regions express specializations for temporal processing at the network, synaptic, and cellular levels, providing striking examples of neural architecture and molecular properties that are clearly related to the function of the circuit and the behavior for which it is utilized. Some of the features of the specialized synaptic physiology in these pathways have been discussed in previous chapters. This chapter will focus primarily on the input pathways and intrinsic properties of neurons in nucleus laminaris (NL) and the medial superior olive (MSO), binaural brainstem nuclei in birds and mammals that first process ITDs. These regions provide some of the clearest examples in neurobiology of how neuronal circuits perform computations.

Our discussion will first explore the nature of ITD cues highlighting some early historical contributions in the field, and we will review the current state of knowledge regarding the anatomy and physiology of both NL and MSO circuitry. We will focus on inhibitory components of both systems, because while inhibition has long been recognized as an important component of ITD processing circuitry, recent work has generated renewed interest in resolving its contribution to ITD processing.

3.35.1.1 Interaural Time Disparity: The Cue for Low-Frequency Sound Localization

The difference in the arrival time of sound to each ear varies systematically with a sound source's position in space along the azimuth (Figure 1(a)). A particular ITD value depends on: (1) the acoustic distance between the ears (interaural distance), (2) the speed of sound in air (or water), and (3) the angle of incidence of the sound to the listener. For example, a sound source emanating from a position in space on the midline with respect to the listener arrives at both ears simultaneously yielding an ITD of 0 μs. This value will systematically increase as the sound is shifted laterally such that a sound source at roughly 90° to the midline will lead in the ipsilateral ear by the maximal ITD, a value that is generally determined by the distance between the two ears. For humans the maximal ITD is ~700 μs (Wightman, F. L. and Kistler, D. J., 1993), while for small mammals such as the gerbil it is ~130 μs (Maki, K. and Furukawa, S., 2005).

These ITDs result in stable interaural phase differences (IPDs) for ongoing periodic sounds such as

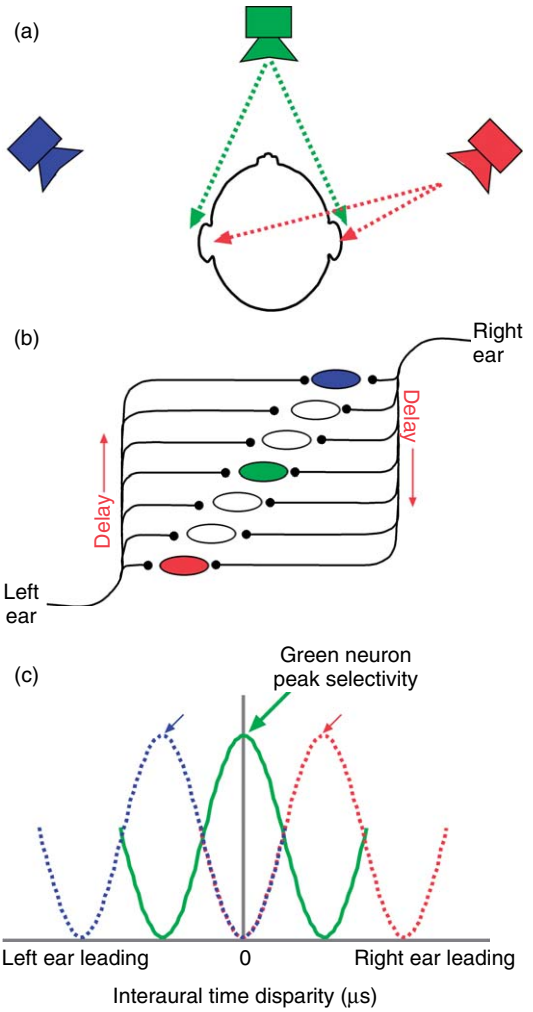

Figure 1 Illustration of the fundamental principles of ITD processing. (a) ITD varies systematically with sound source position. Three sound sources are represented by the three colored speakers. The sound path from the green speaker positioned on the midline is equidistant to each ear, resulting in an ITD of 0 μs. The blue and red speakers will lead in the left and right ears respectively and thus generate large ITDs. The maximum ITD for a human listener is about 700 μs. (b) The Jeffress model for processing ITDs. The ovals represent an array of coincidence detecting neurons and the black lines indicate the input axons to the coincidence detectors. The crucial feature is the increase in axon length (delay lines) from each ear across the array of coincidence detectors. The axon length gradient ensures that each cell in the array is maximally activated at a particular ITD with a value that is determined by the intrinsic delay of the input circuitry. The green neuron, with equal length input axons is selective for an ITD value of 0 μs, while the blue and red neurons prefer ITDs that favor the left and right ear (blue and red sound source positions), respectively. (c) The neural response functions are schematically shown for each of the three colored neurons from panel (b).

tone stimuli. The ongoing phase differences resulting from ITDs provide the principal cue animals use to localize low-frequency sounds in space. The phase difference generated at a given ITD will depend on the frequency of the stimulus. Low-frequency (long wavelength) stimuli generate relatively small IPDs. As frequency increases, the wavelength of the stimulus decreases, thus a greater change in phase (or IPD) will occur per unit time (ITD). Figure 2 illustrates this principle. For simplicity, we will refer to the auditory cue as ITD unless specifically discussing phase. The salience of ITD as a cue for sound location was demonstrated in the early 1900s by Rayleigh L. S. (1907).

Rayleigh's observations defined what is now referred to as the duplex theory of sound localization (Rayleigh, L. S., 1907; Colburn, H. S. and Durlach, N. I., 1978). The duplex theory states that sounds are lateralized on the basis of differences in both arrival time and intensity at the two ears. Arrival time cues are useful at low frequencies where wavelengths are broad and sound intensity is not significantly attenuated by the head. At higher frequencies, when wavelengths are smaller than the interaural distance (roughly 1500 Hz for humans), sound is attenuated by its interaction with the head generating substantial interaural spectral differences (intensity differences, IIDs) between the two ears. ITDs and IIDs are processed in separate parallel pathways that appear to interact through the inhibitory circuitry in both mammals and birds. The circuitry for processing IIDs is beyond the scope of this chapter, but is discussed in Chapter 3.36 (Pollak, G. D. *et al.*, 2002; Pollak, G. D. *et al.*, 2003; Tollin, D. J., 2003).

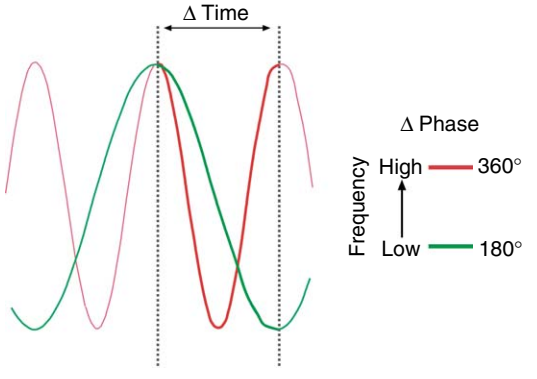

Figure 2 Illustration of the relationship between ITD and IPD. A given ITD defined by the gray dashed lines yields IPDs bold lines that depend on stimulus frequency. In this simple example, the high-frequency stimulus red waveform has a change in phase of 360° for this ITD while the low-frequency green waveform (half the frequency of the red stimulus) has a change in phase of only 180° with the same ITD.

3.35.1.2 Processing Interaural Time Disparities: The Jeffress Model

With the acoustic cues necessary for localizing sounds in azimuth well established, a second major contribution to the field was made by Lloyd Jeffress (1948). He conceived a simple model for the computation of ITDs that has been perhaps the most enduring and influential model in auditory neuroscience. The Jeffress model comprises two major components (Figures 1(b) and 1(c)). The first is an array of coincidence detecting binaural neurons. These neurons require simultaneous or near-simultaneous input from each ear to evoke a maximal response. The second component of his model is a particular arrangement of input axons to the coincidence detectors. The inputs are arranged such that input from a given ear innervates each successive coincidence detector in the array with increasing axon lengths, thus establishing an orderly series of delay lines. A complimentary delay line array is provided by circuitry from the contralateral ear. The model's opposing sets of delay lines compensate for interaural delays such that each consecutive coincidence detecting neuron is optimally responsive to a particular interaural delay and thus systematically shifting locations in space.

3.35.1.3 Processing Interaural Time Disparities: Physiology

These early works by both Raleigh and Jeffress set the stage for decades of behavioral and physiological auditory research. Several studies in the 1960s began to explore auditory brainstem regions that exhibited binaural interactions suggestive of sensitivity to ITD (Hall, J. L., 2nd, 1965; Moushegian, G. *et al.*, 1967; Goldberg, J. M. and Brown, P. B., 1969). Among the most significant of these early pioneering studies was that of Goldberg J. M. and Brown P. B. (1969). Their work represents the first comprehensive physiological study of the MSO. MSO neurons responded primarily to low-frequency stimuli and were remarkably sensitive to ITDs. The authors showed that MSO neurons had spike rates that varied several fold over just a few hundred microseconds shifts in ITD, revealing some of the most temporally sensitive neurons ever observed in the nervous system.

Furthermore, Goldberg and Brown showed that the ITD to which the neurons were most sensitive, referred to as the neuron's "best ITD," was predictable on the basis of the latency of excitatory input from each ear. In other words, the MSO neurons were optimally driven when the time between the ears was adjusted so that the intrinsic delays from the inputs from each ear arrived simultaneously at the MSO neuron. This finding solidified support for the delay line concept proposed by Jeffress and demonstrated that neurons in the mammalian brain are selective for particular ITDs, the localization cue established by Raleigh.

Further investigation of this system in mammals as diverse as cats, kangaroo rats, gerbils, and rabbits has supported and expanded on the major findings of Goldberg and Brown (Hall, J. L., 2nd, 1965; Moushegian, G. *et al.*, 1967; Moushegian, G. *et al.*, 1975; Yin, T. C. and Chan, J. C., 1990; Spitzer, M. W. and Semple, M. N., 1995; Batra, R. and Fitzpatrick, D. C., 1997; Batra, R. *et al.*, 1997b; 1997a). Indeed, the processing of ITDs of airborne sounds appears to be a general feature of auditory systems including insects, reptiles, birds, and mammals (Hoy, R. R. and Robert, D., 1996; Robert, D. *et al.*, 1996; Carr, C. E. *et al.*, 2001). The most comprehensive literature on ITD processing has arisen from studies in birds where behavioral, anatomical, and physiological studies offer a relatively complete picture of sound localization circuitry in the auditory system.

3.35.2 Interaural Time Disparity Processing in Birds

The components of the avian auditory pathway devoted to processing interaural time cues compose what is arguably one of the most elegant and well-understood circuits in the vertebrate nervous system. The elegance of this circuit derives from the remarkable correspondence between its functional role and its anatomical and physiological characteristics. NL is the first nucleus in the avian brainstem to receive information from the two ears and appears to be the initial region where sound location is computed. In addition, it appears that both ITDs and sound frequency are mapped along orthogonal directions in NL.

Current understanding of this circuit relies primarily on studies of two species, the chicken and barn owl. Fortuitously, the data acquired from studies of each species are largely complimentary because the attributes of each preparation are optimal for different but overlapping methods of investigation. For example, studies of the chicken have yielded exceptionally detailed developmental, cell physiological, and anatomical data, whereas the barn owl's remarkable sound localization related behavior has contributed much in relating anatomical and *in vivo* physiological observations to psychophysical and behavioral studies. The general features common to both species will be discussed, but a few of the differences will be highlighted.

3.35.2.1 Inputs to Nucleus Laminaris

In birds, sound is transduced by hair cells of the basilar papilla and relayed to the central nervous system by the auditory nerve (nVIII). nVIII fibers enter the brainstem and bifurcate to innervate two cochlear nuclei (Figure 3). The first, nucleus angularis (NA) is not directly involved in temporal coding, but does interact with this circuit through its connections with inhibitory inputs (see below). The second is nucleus magnocellularis (NM) where large endbulb of Held synaptic complexes from 2 to 4 nVIII fibers make direct contact with the somata of NM cells. This unusually secure synaptic connection preserves the spike timing information encoded in the nVIII and represents one of the early specializations in the ITD coding pathway in birds. There is

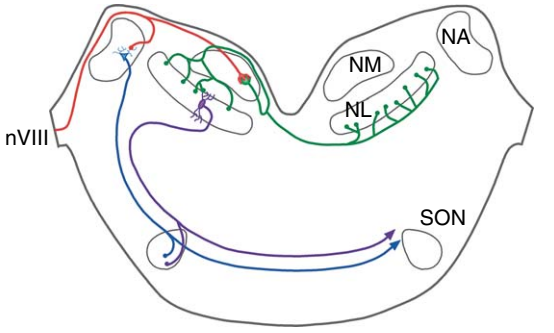

Figure 3 Excitatory pathways in the avian brainstem ITD-processing pathway. Information from the ear is conveyed over the nVIII red line to two cochlear nuclei, nucleus angularis (NA), and nucleus magnocellularis (NM). In NM the nVIII makes large endbulb of Held synapses onto the NM neurons. NM cells in turn project bilaterally to NL green projection. The NM projections to NL are the source of internal delays for ITD processing in birds. Both NA and NL blue and purple lines project to higher-order auditory centers including a fourth brainstem nucleus, the SON. The SON is the primary source of inhibition to all of the brainstem auditory nuclei.

now a vast literature on the nature of this synapse, although much of it is beyond the scope of this chapter. Excellent reviews are presented in Chapter 3.33 and in the writings of Oertel D. (1997) and Trussell L. O. (1997; 1999).

NM cell axons project bilaterally to a third nucleus, NL, the first center to receive binaural input. As with NM, NL is tonotopically organized such that neurons receiving low-frequency NM input are located at the caudolateral pole while high-frequency cells are located rostromedially (Rubel, E. W. and Parks, T. N., 1975). In the chicken, throughout most of its extent, NL is composed of a monolayer of neurons, the exception being the low-frequency caudolateral region which is a few cells thick.

The pattern of NM inputs to NL is a critical feature for the ITD-processing function of NL. Each NM cell axon branches upon exiting the nucleus medially. The ipsilateral branch arcs dorsally, passes back through the nucleus, and then courses rostrally before dipping ventrally to ramify along the dorsal dendrites and on the cell bodies of an isofrequency sheet of NL neurons. Physiological and anatomical studies have shown that the axon length to the ipsilateral NL neurons is equivalent along the isofrequency dimension (Young, S. R. and Rubel, E. W., 1983; Overholt, E. M. *et al.*, 1992). The contralateral collateral from the same NM neuron extends across the midline and branches several times to create an orderly, serial set of axonal branches extending along an analogous isofrequency band of NL neurons. These contralateral collaterals innervate the ventral dendrites and cell bodies of NL neurons within an isofrequency band (Young, S. R. and Rubel, E. W., 1983). This arrangement of innervation, predominantly along the medial to lateral dimension, results in medial laminaris cells receiving contralateral input with the shortest input axons and lateral NL cells the longest. The systematic increase of axon lengths across the nucleus effectively establishes a series of delay lines that compensate for interaural time delays. This corresponds remarkably well to the Jeffress model. One notable exception is that in the chicken NL, the delay line arises solely from the contralateral ear input, rather than bilaterally. Thus, neurons in the lateral NL will respond most vigorously to sounds with ITDs that lead in the contralateral ear (sounds that emanate from contralateral sound fields) and medial laminaris neurons that have receptive fields near the midline. Thus, each NL topographically maps a sound field composed primarily of the contralateral sound field.

The orderly arrangement of input axons across the roughly medial to lateral dimension defines a topography of contralateral delay within NL. Orthogonal to this axis is the tonotopic axis that runs caudolaterally to rostromedially at about 30° to the sagittal plane. Precisely along this tonotopic axis, chicken NL neurons express a gradient of dendrite length (Figure 4) (Smith, D. J. and Rubel, E. W., 1979). In mature animals, dendrite length varies 11-fold from the low- to high-frequency poles of NL (Smith, D. J. and Rubel, E. W., 1979). Low-frequency cells have one or two long primary dendrites that branch profusely, while high-frequency cells have a few short ones. The possible role of this intriguing feature of NL will be discussed in Section 3.35.2.4.

The NL of the barn owl is similar to that described in the chicken, with a few important differences. First, in the high-frequency portion of NL, dendrites of mature barn owl NL neurons are short and are not restricted to the dorsal and ventral poles of the neurons (Carr, C. E. and Boudreau, R. E., 1996; Kubke, M. F. *et al.*, 2002). This may be related to the unusual ability of the barn owl to process ITD information for much higher-frequency signals than other birds and most other mammals (see below). ITDs remain a useful cue up to about 9 kHz and the owl's greatest ITD selectivity is in the range of 4–8 kHz (Knudsen, E. I. and Konishi, M., 1979). A second major difference between the barn owl and chicken is that the barn owl NL is several hundred μm thick and composed of layers of neurons throughout its extent. The input axons to these neurons enter the nucleus at the dorsal or ventral surface and course perpendicularly to the mediolateral trajectory of input axons from the contralateral NM (Carr, C. E. and Konishi, M., 1990). This arrangement of input axons through several layers of NL neurons will be discussed in Section 3.35.2.2, but it represents an expansion of the sound-localization circuitry in this predator, presumably specialized for acoustically localizing prey in the dark.

In addition to the orderly pattern of excitatory inputs to NL, GABAergic inhibitory inputs are abundant (Carr, C. E. *et al.*, 1989; Code, R. A. *et al.*, 1989; Lachica, E. A. *et al.*, 1994; Burger, R. M. *et al.*, 2005). These arise from two sources, a small population of multipolar neurons residing in the neuropil between NM and NL and a prominent projection from the ipsilateral superior olivary nucleus (SON) (von Bartheld, C. S. *et al.*, 1989; Lachica, E. A. *et al.*, 1994;

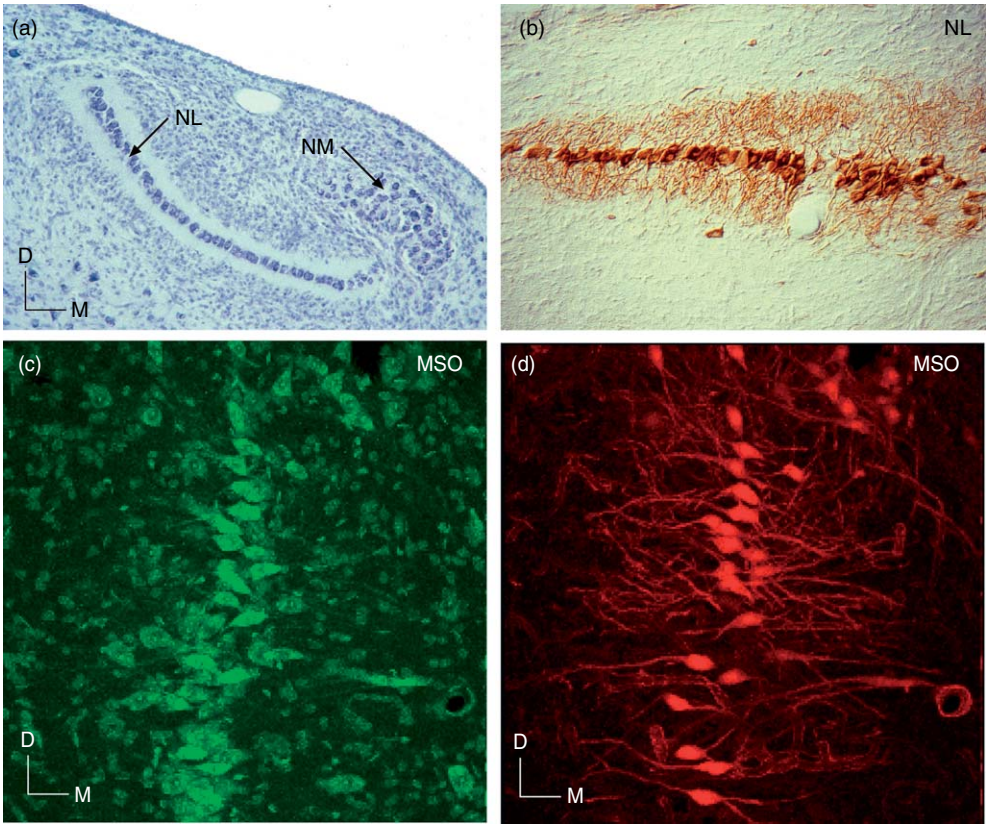

Figure 4 Comparison of NL and MSO neurons. (a) A Nissl-stained section through the auditory brainstem of the chicken showing the laminar structure of NL and the neighboring ipsilateral NM. (b) The dendrite length gradient in NL can be clearly observed in the section through NL stained for MAP2 antigen. Higher best frequency neurons are to the left, lower BF NL cells are to the right. Additionally, one can appreciate the dorsoventrally oriented bipolar dendrites. (c) Neurons of the Gerbil MSO can be seen clustered along a dorsoventral running axis in this fluorescent Nissl-stained section. (d) The bipolar mediolaterally oriented dendrites of rhodamine conjugated dextran-labeled MSO neurons in the same section as that shown in (c).

Westerberg, B. D. and Schwarz, D. W., 1995; Yang, L. *et al.*, 1999; Burger, R. M. *et al.*, 2005). The functional impact of this inhibitory input has been the focus of intense study and current understanding of inhibition's role in the computation of ITDs will be discussed in some detail further in this chapter.

3.35.2.2 Encoding of Interaural Time Disparities in Nucleus Laminaris

NL's primary function appears to be the computation and topographic representation of ITDs across the nucleus. The most compelling data available on a topographic ITD representation has derived from studies of the barn owl nucleus laminaris and *in vitro* data from the chicken (Parks, T. N. and Rubel, E. W., 1975; Sullivan, W. E. and Konishi, M., 1986; Carr, C. E. and Konishi, M., 1990; Overholt, E. M. *et al.*, 1992; Joseph, A. W. and Hyson, R. L., 1993). The suggestion that innervation pattern of NL from the contralateral NM may represent a Jeffress-type delay line was first suggested for the chicken by Parks T. N. and Rubel E. W. (1975) where the topography of these connections was initially described. Later physiological and anatomical work in both the barn owl and chicken has confirmed the hypothesis of Parks T. N. and Rubel E. W. (1975).

While the anatomical substrate of the delay line that generates the topographic representation was identified and described in the chick by Young S. R. and Rubel E. W. (1983) (Figure 5), the contribution of delay lines to the resultant topographic representation of ITD was demonstrated physiologically *in vivo* by a sequence of papers from the Konishi lab (Sullivan, W. E. and Konishi, M., 1986; Carr, C. E. and Konishi, M., 1990). In the first paper, roughly dorsal to ventral electrode penetrations were made through NL transecting the contralateral NM axon

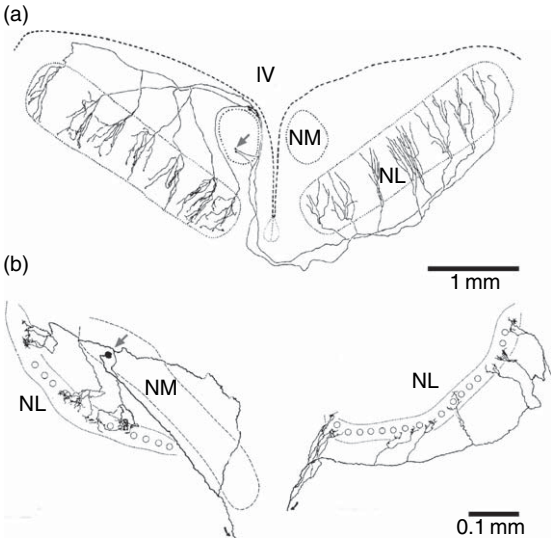

Figure 5 A comparison of the inputs from NM to NL in the barn owl and chicken reveals the exquisite architecture of the avian ITD-coding system. (a) Reconstruction of projections from two barn owl NM neurons to their targets in NL and in (b) reconstruction of an NM neuron projection in the chicken. In both barn owl and chicken, the contralateral projections innervate medial NL neurons with the shortest axon segments while the lateral NL cells receive the longest NM axon length inputs. In the barn owl, the orderly and opposing innervation from the dorsal and ventral borders of NL by NM axons may lead to additional sources of delay. NM neuron somas are labeled by gray arrows in both panels. (a) From Carr, C. E. and Konishi, M. 1990. A circuit for detection of interaural time differences in the brain stem of the barn owl. J. Neurosci. 10, 3227–3246. (b) From Young, S. R. and Rubel, E. W. 1983. Frequency-specific projections of individual neurons in chick brainstem auditory nuclei. J. Neurosci. 3, 1373–1378.

length gradient obliquely. Sullivan W. E. and Konishi M. (1986) demonstrated that as the electrode advanced ventrally (and roughly across the gradient of medial to lateral input axon lengths) the ITD for eliciting a maximum field potential shifted systematically toward the contralateral ear.

A later study by Carr C. E. and Konishi M. (1990) in which recordings were made from NM axons in addition to NL cells, demonstrated that when electrode penetrations were made perpendicular to the mediolateral running plexus of NM input axons in the ventral NL, delays increased or decreased with depth, depending on whether the axon was from ipsilateral or contralateral NM, respectively. In addition, a given interaural phase delay was often represented more than once in a single penetration. These authors have suggested that in the barn owl, the topographic representation of the entire range of ITDs is represented along the dorsal–ventral axis of NL, and this representation is repeated many times along the predominantly mediolateral dimension that is orthogonal to the tonotopic dimension. In other words, the layered expansion of NL in barn owls could generate an additional source of delay lines not present in other bird species.

The presence of delay lines in the bird auditory pathway was directly demonstrated by *in vitro* chick brainstem slice studies in the Rubel lab (Overholt, E. M. *et al.*, 1992; Joseph, A. W. and Hyson, R. L., 1993). Hyson and colleagues recorded postsynaptic field potentials from NL neurons while systematically shifting the timing of stimulated inputs from the ipsilateral and contralateral NM. In these studies, a dramatic difference was observed when stimulating the ipsilateral versus contralateral input to NL neurons. Increasing delays were observed as the electrode was moved along an isofrequency line of NL neurons; that is, rostrolaterally parallel to the main axis of input axons thus confirming the source of input delays. Consistent with predictions from the anatomical observations of Young S. R. and Rubel E. W. (1983), latencies of the postsynaptic responses to ipsilateral stimulation did not vary as the electrode is moved from medial to lateral. On the other hand, the latencies of postsynaptic responses to contralateral stimulation systematically increased along the delay line dimension. Furthermore, these studies showed that NL cells were most optimally driven by binaural inputs timed to compensate for the mismatch in delay from each NM.

3.35.2.3 Intrinsic Properties of Nucleus Laminaris Neurons Specialized for Interaural Time Disparity Computation

The studies reviewed above provided the anatomical and physiological groundwork for a next generation of studies that have explored the unique specializations of intrinsic physiological properties in NM and NL that contribute to ITD calculations. Perhaps the most ubiquitous attribute of neurons involved in processing temporal aspects of auditory stimuli is the prevalence of potassium conductances that are suited to enhance temporal encoding. These include both a low-threshold potassium conductance (K^+_{LVA}) associated with Kv1 family channel subunits and a high-threshold (K^+_{HT}) conductance associated with Kv3 family channel subunits.

The K^+_{LVA} conductances have been investigated in a large number of auditory neurons (Oertel, D., 1983; Manis, P. B. and Marx, S. O., 1991; Banks, M. I. and Smith, P. H., 1992; Reyes, A. D. *et al.*, 1994; Zhang, S. and Trussell, L. O., 1994; Brew, H. M. and Forsythe, I. D., 1995; Smith, P. H., 1995; Reyes, A. D. *et al.*, 1996; Rathouz, M. and Trussell, L., 1998; Bal, R. and Oertel, D., 2001; Adamson, C. L. *et al.*, 2002; Svirskis, G. *et al.*, 2002; Svirskis, G. *et al.*, 2003; Kuba, H. *et al.*, 2005; Scott, L. L. *et al.*, 2005). The channels underlying this conductance are activated at voltages at or just above rest and have several influences on information processing. First, the strong outward conductance causes a reduced membrane input resistance thus shortening the time constant of the membrane. This has the dual effect of reducing the time course of voltage changes from a given input and correspondingly reducing the time window during which inputs can summate. Second, these neurons typically respond to sustained depolarizing currents with a single action potential, allowing the membrane to recover quickly from an excitatory input. This property has been observed in many auditory neurons involved in temporal processing. A classic example of responses in a mammalian medial nucleus of the trapezoid body (MNTB) neuron from a study by Brew H. M. and Forsythe I. D. (1995) is shown in Figure 6. A third effect of this conductance is to raise the neuron's threshold. Together, these effects may increase the requirement for inputs to be coincident in order to evoke a postsynaptic action potential, a property which provides improved temporal processing ability advantageous for the encoding of ITDs (Carney, L. H., 1992; Rothman, J. S. *et al.*, 1993).

The channels underlying the K^+_{HT} conductances activate at high voltages in the range of −20 mV and thus may only be activated by action potentials (Gan, L. and Kaczmarek, L. K., 1998; Rudy, B. and McBain, C. J., 2001). These channels' protein subunits or their mRNAs have been shown to be highly expressed in both NL and NM (Parameshwaran, S. *et al.*, 2001; Parameshwaran-Iyer, S. *et al.*, 2003; Lu, Y. *et al.*, 2004), as well as in mammalian time-coding neurons (Perney, T. M. *et al.*, 1992; Perney, T. M. and Kaczmarek, L. K., 1997; Grigg, J. J. *et al.*, 2000). The K^+_{HT} conductances confer upon neurons the ability to rapidly repolarize following an action potential and thus the primary role of K^+_{HT} currents appears to be the preservation of high-frequency firing (Brew, H. M. and Forsythe, I. D., 1995; Gan, L. and Kaczmarek, L. K., 1998; Wang, L. Y. *et al.*, 1998). Several studies have shown that in the presence of low concentrations of tetraethylammonium chloride (TEA) which blocks K^+_{HT}, cells fail to sustain the high-firing frequencies typically achieved by temporal coding neurons (Brew, H. M. and Forsythe, I. D., 1995; Wang, L. Y. *et al.*, 1998). Figure 6 shows that a TEA-sensitive conductance in MNTB cells contributes to the brevity of action potentials. Furthermore, recent studies suggest that K^+_{HT} conductances can be modulated through phosphorylation in an activity-dependent manner (Macica, C. M. *et al.*, 2003; Song, P. *et al.*, 2005). This finding suggests the possibility that this conductance may be tuned to optimally preserve temporal fidelity over a large range of firing frequencies (Song, P. *et al.*, 2005).

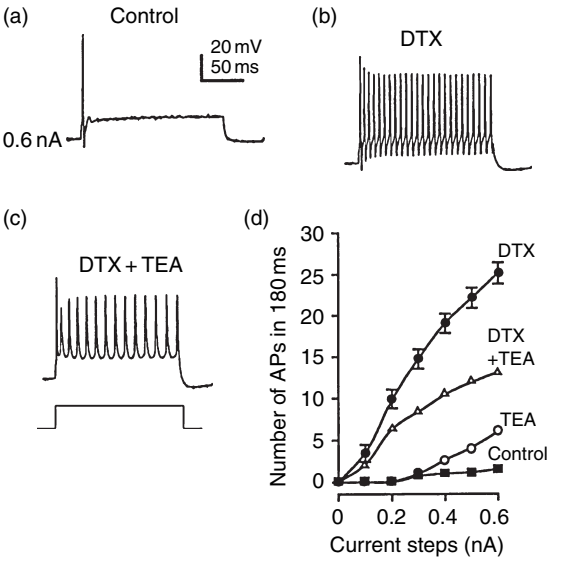

Figure 6 Potassium currents enhance signal processing in time-coding neurons. Shown are responses of MNTB neurons to current injections. (a) In the control condition, cells typically respond to depolarizing current steps with a single rapid action potential followed by a steady-state depolarization. The steady-state response is normally highly outward rectified (not shown). (b) When DTX, a Kv1 subunit specific blocker, is applied to the neuron, multiple spiking is evoked by the same current pulse. (c) Shows that by TEA application, high-threshold K^+ channels play an additional role in controlling membrane voltage. (d) Shows the firing rates across the population for the conditions in (a) through (c) and the TEA alone condition for two additional cells. Adapted from Brew, H. M. and Forsythe, I. D. 1995. Two voltage-dependent K^+ conductances with complementary functions in postsynaptic integration at a central auditory synapse. J. Neurosci. 15, 8011–8022. Change to the current values from original was made at the request of H. Brew.

The impact of K^+_{LVA} conductances on phase-locking and modulation of firing frequency in NL was investigated by Reyes A. D. *et al.* (1996). Reyes and colleagues recorded evoked excitatory postsynaptic conductances (EPSCs) in NL, and then, based on these recordings, computed model input trains and injected the summed current into the cells through a patch pipette. This strategy allowed the experimenters to model variations in the size, number, and temporal properties of the inputs. They were able to show that as stimulus frequency increased, a reduction of the number and an increase in size of the inputs was necessary to maintain high firing rates and phase-locked discharges in NL cells. They demonstrated that NL neurons characteristically possess a large low-threshold potassium conductance and that this conductance was crucial for temporal coding. NL neurons in which this current was pharmacologically blocked or other brainstem neurons that did not possess this conductance, were unable to phase-lock to high input frequencies.

Work by Ohmori and colleagues investigated the tonotopic distribution of Kv1.1 type potassium channel subunits, which are often incorporated into voltage gated K^+ channels that underlie K^+_{LVA} conductances. Using both physiological and immunohistochemical methods, they show that Kv1.1 subunits are not distributed evenly across the tonotopy of NL. NL cells in the mid- and high-frequency range appear to express Kv1.1 subunits and the associated conductance at higher levels than low-frequency neurons. Correlated with this effect is the observation that the middle-frequency NL neurons, the subset that physiologically had the strongest K^+_{LVA} conductances, appear to have the smallest coincidence window. The authors suggested that these findings may explain behavioral data showing that sound localization is most precise in the middle-frequency range for many birds (Kuba, H. *et al.*, 2005).

An additional important observation from this series of studies was the demonstration that the input properties vary across the tonotopy such that low-frequency cells produce Excitatory post synaptic potentials (EPSPs) with a longer time course than their mid- and high-frequency counterparts. The long EPSP duration was attributable to dendritic filtering of low-frequency NL cells that results from the large surface area of dendrites (Rall, W., 1969; Koch, C. and Segev, I., 2000; Kuba, H. *et al.*, 2005). A possible consequence of this filtering property is that it may enhance the electrical isolation of dorsal and ventral dendrites and, thus, the inputs from either ear from each other. This finding is significant because it is the first direct data to support the notion that the dendrite length gradient in NL is an adaptation for ITD processing of particular stimulus frequencies.

A fascinating assessment of the possible contribution of NL dendrites to ITD computation was made in an influential modeling study (Agmon-Snir, H. *et al.*, 1998). These authors proposed that the segregation of the ipsilateral and contralateral inputs to the dorsal and ventral dendrites, respectively, of NL neurons provides semi-isolated electrical compartments in which a series of inputs arriving near-simultaneously will add sublinearly within one electrical compartment. On the other hand, inputs arriving on separate dendrites will sum linearly in the soma. This mechanism could greatly enhance coincidence detection. Put simply, two inputs that arrive on separate dendrites and provide just enough current necessary to reach threshold would add sublinearly in a single dendrite and thus not generate a postsynaptic action potential. This mechanism would function to enhance a cell's responsiveness to binaural inputs, while suppressing the signaling of responses from coincident monaural input. The model also provided a rationale for the reduction of dendrite length with increasing frequency. Due to the amount of temporal error in phase-locking (or jitter), long dendrites, with longer duration membrane time constants, may expand their inputs in time and cause excess monaural summation at high frequencies where the stimulus period is brief, relative to the temporal jitter.

3.35.2.4 The Role of Inhibition in Nucleus Luminaris Function

The release of GABA in both NM and NL has unusual and important properties. GABA-receptor activation evokes a depolarizing response in these neurons. This property, first discovered by Hyson R. L. *et al.* (1995) in NL, is due to an unusually high internal Cl^- concentration. The reversal potential for the Cl^- conductance through $GABA_A$ receptors has been reported to be -25 and -37 mV by two separate studies using gramicidin perforated patch-clamp recording of NM cells (Lu, T. and Trussell, L. O., 2001; Monsivais, P. and Rubel, E. W., 2001). Depolarizing responses to GABA are not unusual at early stages of development in the auditory system or in other central neurons (Ben-Ari, Y. *et al.*, 1990; Cherubini, E. *et al.*, 1990; Kandler, K. and Friauf, E., 1995; Ehrlich, I. *et al.*, 1999; Kakazu, Y. *et al.*, 1999), but

are normally rapidly converted to hyperpolarizing responses. In mammalian auditory systems this generally occurs around the time of onset of hearing (Kandler, K. and Friauf, E., 1995; Smith, A. J. *et al.*, 2000; Magnusson, A. K. *et al.*, 2005). The precise mechanism underlying this shift is unknown, but is likely due to a change in Cl^- transporter expression (Kakazu, Y. *et al.*, 1999). In the chicken, depolarizing responses to GABA have been recorded well beyond hearing onset and appear to persist into maturity (Hackett, J. T. *et al.*, 1982; Jackson, H. *et al.*, 1982; Hyson, R. L. *et al.*, 1995; Yang, L. *et al.*, 1999; Monsivais, P. *et al.*, 2000; Lu, T. and Trussell, L. O., 2001).

What functional benefit is gained by this unusual property? In a series of studies from our laboratory, Monsivais and colleagues (Yang, L. *et al.*, 1999; Monsivais, P. *et al.*, 2000; Monsivais, P. and Rubel, E. W., 2001) showed that despite the depolarizing response to GABA, this input is generally inhibitory although occasional spiking from GABAergic input has been observed *in vitro* (Lu, T. and Trussell, L. O., 2001; Lu, Y. *et al.*, 2005). Indeed, Monsivais P. and Rubel E. W. (2001) showed that GABAergic depolarization into a superthreshold voltage range maintains its inhibitory function, and even exceeds the inhibitory potency that would derive from equal strength hyperpolarizing inputs. This depolarizing and potent inhibitory response is mediated through three cooperative mechanisms.

First, GABA release at NM or NL activates $GABA_A$ channels generating a Cl^- conductance. High stimulation rates of inhibitory inputs to NM cause Ca^{2+} accumulation in GABAergic terminals resulting in a long-lasting postsynaptic plateau inhibition characterized by asynchronous release of GABA (Lu, T. and Trussell, L. O., 2000). The outward flux of Cl^- ions depolarizes the cell membrane activating strong K^+_{LVA} conductances that dramatically lower the input resistance and thus provide a shunting inhibition for subsequent excitatory inputs. Finally, the slow and sustained GABA-induced depolarization causes inactivation of voltage gated Na^+ channels and, as a consequence, threshold shifts to depolarized values (Monsivais, P. and Rubel, E. W., 2001). Our recent study suggested that excessive GABA-evoked depolarization might be limited by $GABA_B$ receptor activation on the GABAergic terminals. $GABA_B$ receptor activation at these sites reduces the release of transmitter and subsequently generates less postsynaptic depolarization (Lu, Y. *et al.*, 2005).

Funabiki K. *et al.* (1998), in the Ohmori lab, tested the hypothesis that GABAergic input to NL improves coincidence detection as well. In an elegant series of experiments, they simulated binaural inputs by current injection or direct stimulation of NM axons and varied the interval between inputs to simulate a range of ITDs. They showed that during GABA application, the range of binaural intervals that evoked responses in the NL neurons (or response window) was reduced by 70%. This study clearly demonstrated GABA's potentially advantageous effect on the computational properties of NL.

To date, there have been no *in vivo* studies in birds to directly address the role of endogenous GABAergic input to the temporal coding nuclei. However, several studies have been done that underscore the potentially critical influence inhibition may have on ITD coding. Among the most important of these, Peña and colleagues in the Konishi lab published a pair of studies using loose-patch recording of NM and NL neurons providing superior isolation of responses. The NL recordings explored the stability of ITD tuning when neurons were challenged with a range of intensity changes to the two ears such that levels were shifted simultaneously in both ears (diotically) or differentially in each ear (dichotically) (Pena, J. L. *et al.*, 1996; Viete, S. *et al.*, 1997). Figure 7 shows that NL neurons possess a remarkable ability to maintain their best ITD (the ITD evoking the strongest response) and large firing-rate modulations with ITD over a large dynamic range of diotically presented intensity changes (Pena, J. L. *et al.*, 1996). Additionally, in the second paper, Viete S. *et al.* (1997) showed that for broadband stimuli, a neuron's best ITD remained fairly stable when the input intensity to either ear was unequal, suggesting that the system may include a mechanism to correct for differences in input strengths. These authors suggested that inhibition might provide the input necessary to preserve the stability of the ITD selective response under a broad range of conditions, although in their hands, evidence for such a mechanism was not forthcoming.

Our recent studies on the detailed anatomy of the GABAergic input to these nuclei from the SON led to predictions about a specific inhibitory mechanism for the observations noted earlier and further suggest that the inhibitory components of the ITD processing circuitry may have a fundamental role in ITD processing (Burger, R. M. *et al.*, 2005). In the chicken, most of the inhibitory input to the cochlear nuclei and NL is provided by the ipsilateral SON (Lachica,

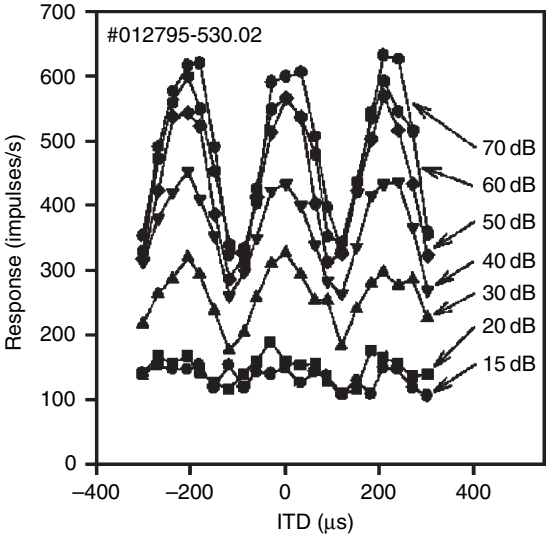

Figure 7 NL neurons possess a remarkable ability to maintain ITD selectivity over a broad dynamic range. In this figure, Pena and colleagues showed that NL neurons preserve their best ITD and a fairly large dynamic response over a large range of binaurally presented intensity changes. These data suggest that some mechanism, perhaps inhibition, may adjust the gain of the NL neuron's responses, allowing it to be selective at low intensities and preventing saturation at high intensities. Reproduced from Pena, J. L., Viete, S., Albeck, Y., and Konishi, M. 1996. Tolerance to sound intensity of binaural coincidence detection in the nucleus laminaris of the owl. J. Neurosci. 16, 7046–7054.

E. A. *et al.*, 1994; Westerberg, B. D. and Schwarz, D. W., 1995; Yang, L. *et al.*, 1999; Burger, R. M. *et al.*, 2005). The SON, in turn, receives its input from three sources, NA, NL, and the contralateral SON (Yang, L. *et al.*, 1999). The NA and NL input is glutamatergic and excitatory, and the contralateral SON input is likely to be inhibitory. Thus, the inhibitory circuitry of the avian auditory system is composed of a negative feedback loop on each side of the brainstem. In addition, these two feedback circuits appear to be negatively coupled to one another (Figure 8).

This anatomical arrangement provides clues as to how the system may work. We developed a conceptual model that suggested that this arrangement would provide a mechanism to preserve ITD encoding by equalizing the input strength to NL (Burger, R. M. *et al.*, 2005). A computational model went further in testing this hypothesis in a model avian auditory brainstem network using realistic biological parameters (Dasika, V. K. *et al.*, 2005).

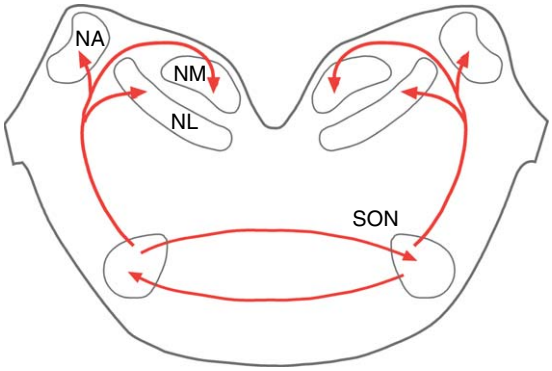

Figure 8 The inhibitory circuitry of the avian auditory brainstem. The majority of inhibitory input to the time-coding system emanates from the predominantly GABAergic SON. The SON which receives excitatory input from both NA and NL provides inhibition back to all ipsilateral brainstem nuclei forming an inhibitory feedback loop. These parallel feedback loops are coupled by the crossed reciprocal and putatively inhibitory connection between the SONs. These negatively coupled feedback circuits may be involved in offsetting bilateral differences in input strength to NL.

3.35.3 Interaural Time Disparity Processing in the Medial Superior Olive

The MSO in mammals receives a similar complement of inputs to that of NL in avians. However, important differences exist which raise interesting comparative questions as to the nature of ITD processing in MSO. In this section, we will first discuss the known anatomy and physiology of the MSO leading to some current issues in the field of ITD processing in the final section.

3.35.3.1 Mammalian Interaural Time Disparity-Encoding Circuitry

The MSO receives four principal inputs, one excitatory and one inhibitory, driven from each ear (Figure 9). The excitatory inputs derive bilaterally from the spherical bushy cells of the anteroventral cochlear nucleus (AVCN) where neurons specialized to faithfully transmit temporal aspects of the acoustic signal project to the MSO (Stotler, W. A., 1953; Glendenning, K. K. *et al.*, 1985; Cant, N. B. and Hyson, R. L., 1992; Smith, P. H. *et al.*, 1993). For a thorough review of superior olive anatomy see Thompson A. M. and Schofield B. R. (2000). MSO neurons, like their avian NL counterparts, have bipolar dendrites oriented roughly in the mediolateral plane, with each dendrite receiving input from

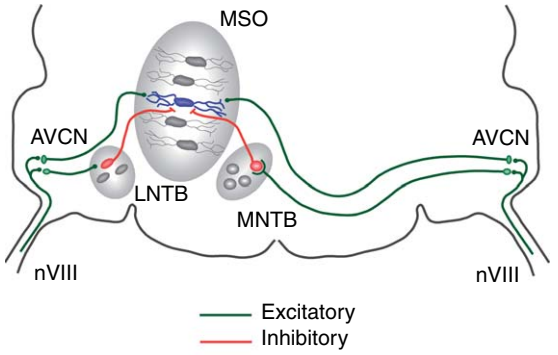

Figure 9 Input pathways to the MSO. The MSO receives excitatory input green pathways from both ears via bushy cells of the AVCN where nVIII inputs convey phase-locked discharges with large endbulb of Held synapses. Inhibition from both ears is also derived from input circuitry that is specialized to preserve temporal information. Input from the contralateral ear is conveyed via the glycinergic MNTB where bushy cell axons make large Caylx of Held synapses onto MNTB neuron somas. The ipsilateral inhibitory input is derived from the LNTB where enlarged synaptic endings from AVCN neurons appear to be specialized for temporal encoding.

its proximal ear (Figure 4) (Stotler, W. A., 1953; Smith, P. H. *et al.*, 1993).

The inhibitory input from the contralateral ear is derived from the medial nucleus of the trapezoid body (MNTB) (Kuwabara, N. and Zook, J. M., 1992; Smith, P. H. *et al.*, 1998). The glycinergic MNTB receives input from the anteroventral cochlear nucleus (AVCN) through large caliciform synapses that convert the precisely timed excitatory input into a precisely timed inhibitory output. The ipsilateral inhibition to the MSO is derived from the lateral nucleus of the trapezoid body (LNTB) where similar large synapses from AVCN bushy cells drive its glycinergic inhibitory output (Cant, N. B. and Hyson, R. L., 1992; Kuwabara, N. and Zook, J. M., 1992; Spirou, G. A. *et al.*, 1998).

A fundamental component of ITD-encoding circuitry according to the Jeffress hypothesis is an orderly series of input delay lines. In birds, NM input to the contralateral NL exhibits a clear anatomical axon length gradient that corresponds to the orderly representation of interaural phase delays. The evidence for delay lines in mammals is controversial. In the cat MSO, some compelling data suggests that the input axons from the contralateral ear may be arranged to generate delay lines, such that the rostral MSO cells receive the shortest length input collateral and the caudal cells receive the longest (Smith, P. H. *et al.*, 1993; Beckius, G. E. *et al.*, 1999). This anatomical arrangement agrees fairly well with the physiologically observed rough topography of ITD representation reported in the cat (Yin, T. C. and Chan, J. C., 1990). However, data from both anatomical studies shows that many input axons innervate only small segments of the MSO and not the entire extent of the nucleus as they do in NL. In addition, there have not been similar systematic physiological studies of the inputs to MSO at the level of those in NL (Sullivan, W. E. and Konishi, M., 1986; Carr, C. E. and Konishi, M., 1990; Overholt, E. M. *et al.*, 1992; Joseph, A. W. and Hyson, R. L., 1993) to confirm the presence of functional delay lines as a general feature in mammals.

3.35.3.2 Response Properties of Medial Superior Olive Neurons

The classic work of Goldberg J. M. and Brown P. B. (1969) was the first thorough study of the MSO role in ITD processing. Goldberg and Brown showed that MSO neurons in the dog were: (1) excited by input to both ears, (2) phase-locked to the stimulus waveform, and (3) optimally driven by binaural input with a particular delay that could be predicted based on the ITD required for the coincidence of monaural delays from each ear. They also observed several features of MSO neural responses that they attributed to inhibition, such as frequency selectivity, nonmonotonic input/output functions when driven by sound to one or both ears, and binaural firing rates that fell below the firing rate to either ear alone at the worst ITD (the ITD evoking the lowest firing rate).

The presence of brainstem neurons that process ITDs in a similar fashion to those observed in the dog have been documented in the cat, rabbit, gerbil, and kangaroo rat (Moushegian, G. *et al.*, 1967; Moushegian, G. *et al.*, 1975; Yin, T. C. and Chan, J. C., 1990; Spitzer, M. W. and Semple, M. N., 1995; Batra, R. and Fitzpatrick, D. C., 1997; Batra, R. *et al.*, 1997a; 1997b). In most of these studies the dominant class of MSO neurons exhibited evidence of phase-locked excitatory input from each ear and responded selectively to ITD selectivity to varying binaural stimuli. This suggests that most MSO neurons derive their response properties by cross-correlation of the phase-locked excitation from each ear.

A series of studies from Batra and colleagues (Batra, R. and Fitzpatrick, D. C., 1997; Batra, R. *et al.*, 1997a; 1997b) investigated ITD processing in the superior olivary complex. An important finding

of these studies was that coincidence of excitation from one ear and inhibition from the opposite ear also can impart ITD sensitivity on a neuron. Such neurons were referred to as troughers, following the nomenclature of Kuwada S. and Yin T. C. (1983) and Yin T. C. and Kuwada S. (1983a; 1983b), and were also observed in earlier studies of the LSO (Finlayson, P. G. and Caspary, D. M., 1991; Joris, P. X. and Yin, T. C., 1995). Spiking in trougher neurons is suppressed at a particular ITD regardless of stimulus frequency. Thus, these neurons are inactivated by coincidence of their inputs. However, it remains inconclusive whether or not this class of neurons resides within the MSO proper, but rather, may be the predominant ITD selective cell type in the neighboring lateral superior olive.

3.35.3.3 Intrinsic Properties of Medial Superior Olive Neurons

MSO neurons share several morphological and physiological properties with NL cells. Similar to other neurons that are specialized for processing temporal information (as cited earlier), injection of depolarizing current into principal MSO cells typically results in a single action potential followed by a sustained depolarization (Smith, P. H., 1995). The sustained portion of the response shows strong outward rectification. Application of 4-AP increases the number of action potentials and reduces the degree of rectification. This suggests that the large K^+_{LVA} type currents dominate the intrinsic membrane voltage responses in MSO neurons (Smith, P. H., 1995).

A study utilizing both physiological and modeling methods tested the role of K^+_{LVA} in signal detection in the presence of noisy inputs. Using a similar approach to that used by Reyes A. D. *et al.* (1996) in NL, Svirskis G. *et al.* (2002) injected subthreshold simulated excitatory postsynaptic conductances (EPSGs) as signals in a background of noisy subthreshold currents into normal and dendrotoxin (DTX)-treated MSO cells. DTX is a specific blocker of Kv1 family subunit containing channels (Robertson, B. *et al.*, 1996). They used a spike-triggered reverse correlation paradigm to determine the optimal current waveform to evoke spiking and found that control cells required very rapid inward currents, indicating a brief integration window. In DTX-treated cells the integration window was broader and the phase-locking to simulated EPSGs was poor. Thus, NL and MSO possess similar intrinsic mechanisms to enhance ITD selectivity.

In a later paper Svirskis G. *et al.* (2004) showed that at rest, many voltage-gated Na^+ channels are inactivated in MSO cells. Spike-triggered reverse correlations showed that MSO neurons fired optimally following a brief hyperpolarizing current. Manipulations of the Na^+ current showed that brief hyperpolarizing inputs have a role in releasing Na^+ channels from inactivation, thereby increasing the spike probability for a subsequent depolarizing input. Thus, the Na^+ channel properties in MSO cells may interact with inhibitory inputs to shape the coincidence window.

3.35.3.4 The Role of Inhibition in the Medial Superior Olive

Speculation on the contribution of inhibition in MSO responses has persisted in the literature since Goldberg J. M. and Brown P. B. (1969) noted that the firing rate to binaural stimuli that were at the worst ITD were below the rates evoked by stimulation of either ear alone. Similar observations have been noted in subsequent studies (Yin, T. C. and Chan, J. C., 1990; Spitzer, M. W. and Semple, M. N., 1995; 1998). Abundant anatomical evidence shows direct innervation of the MSO by both the glycinergic MNTB and the LNTB (Cant, N. B. and Hyson, R. L., 1992; Kuwabara, N. and Zook, J. M., 1992; Smith, P. H. *et al.*, 1998).

Investigation of these inputs has been made in slice preparations of both gerbil and rat (Grothe, B. and Sanes, D. H., 1993; 1994; Smith, A. J. *et al.*, 2000; Magnusson, A. K. *et al.*, 2005). Grothe B. and Sanes D. H. (1994) showed that glycinergic input suppressed firing of MSO cells *in vitro* at particular stimulus intervals between shocks to ipsilateral and contralateral inputs. Studies by Smith A. J. *et al.* (2000) in the rat and Magnusson A. K. *et al.* (2005) in the gerbil investigated the development of inhibitory input to the MSO and showed that between the early postnatal period and the week following the onset of hearing, inhibitory inputs to MSO switch from slow depolarizing and predominantly GABAergic to relatively fast, hyperpolarizing, and predominantly glycinergic inputs. A similar developmental pattern has been described in the neighboring lateral superior olive (LSO), which receives collateral MNTB input (Kandler, K. and Friauf, E., 1995; Kotak, V. C. *et al.*, 1998; Nabekura, J. *et al.*, 2004; Magnusson, A. K. *et al.*, 2005). In the LSO the developmental conversion of inhibitory inputs represents a gradual switch from GABA to glycine transmitter expression within individual inhibitory terminals rather than a replacement

of GABAergic input axons by glycinergic ones (Nabekura, J. *et al.*, 2004).

The first study to test the role of inhibition in MSO coding *in vivo* by manipulating the glycinergic receptor activation yielded striking results. These results suggest a critical difference between avian and mammalian strategies for computation of ITDs. Brand A. *et al.* (2002) recorded from the gerbil MSO using multibarrel microelectrodes that allowed them to block the glycinergic input to MSO neurons with strychnine during recordings. Their data revealed that in the presence of strychnine, all MSO neurons had maximal responses at ITD values near 0 μs (Figure 10). In control recordings, on the other hand, most neurons had a best ITD favoring sounds leading in the contralateral ear and outside the physiological range (the maximum range of ITD experienced by the animal under normal conditions). These data suggest that ITD processing in the gerbil may not rely on delays imposed on MSO by input axons but rather, the inhibitory inputs provided by the MNTB and/or the LNTB shape the selectivity.

Brand A. *et al.* (2002) supported their conclusions with computational modeling that showed that interaction between very rapid glycinergic inputs and the glutamatergic AVCN inputs is sufficient to generate the normal ITD responses. Since inhibitory inputs possessing such rapid kinetics have not been observed in intracellular studies of MSO neurons (Smith, A. J. *et al.*, 2000; Magnusson, A. K. *et al.*, 2005), further studies will be required to resolve exactly how inhibition imparts its apparently critical contribution to MSO response properties.

3.35.3.5 The Neural Code for Interaural Time Disparity in Mammals

A second important finding of the Brand A. *et al.* (2002) study is that the peaks of the ITD functions in the control condition almost always occurred outside of the physiological range of ITDs. Similar results have been observed in the gerbil DNLL and the guinea pig inferior colliculus (McAlpine, D. *et al.*, 2001; Seidl, A. H. and Grothe, B., 2005). These organisms share the characteristics of having both, low-frequency hearing and small heads. As a consequence, the role of inhibition identified in the gerbil raises considerable doubt regarding the notion that ITD processing is simply a function of coincidence of binaural excitatory delays.

The recent progress discussed earlier has compelled researchers in the field to re-evaluate the nature of ITD representation in the mammalian nervous system. This topic has been thoroughly and clearly discussed elsewhere (Grothe, B., 2003; McAlpine, D. and Grothe, B., 2003) and the arguments will not be recounted here, but the discussion rests on two possible, and not mutually exclusive, strategies of ITD representation in the nervous system.

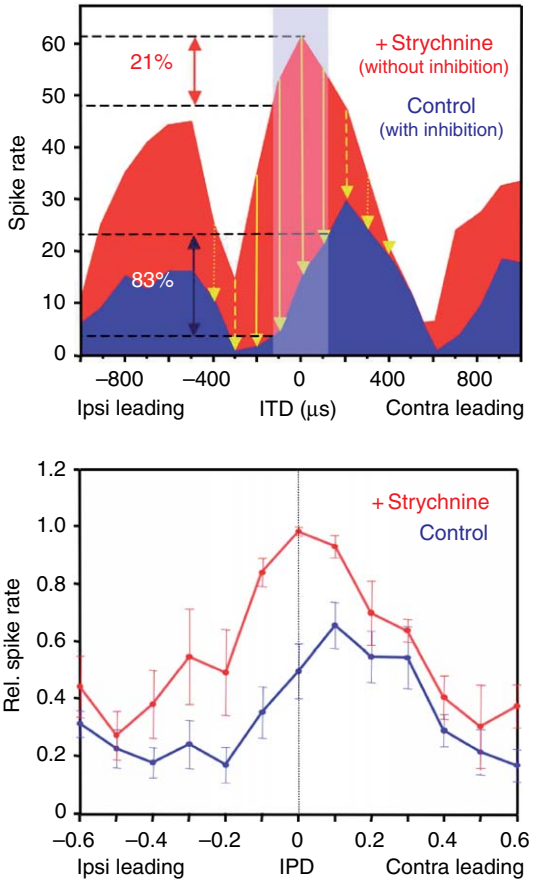

Figure 10 Inhibition shapes ITD functions in MSO. The top panel shows the ITD response functions of an MSO neuron before blue function and after red function application of strychnine, a glycine-receptor antagonist. The control condition data indicate that the peak response falls outside the range of naturally occurring ITDs shaded area but that the steepest slope of the function falls across zero ITD. When strychnine was applied, the neuron shifted its best ITD to near-zero, and had a rather small dynamic response within the physiological range. In the lower panel, the population data suggests that a primary consequence of inhibition in the MSO is to shift the location of the peak (or the slope) of ITD functions toward ITDs that lead in the contralateral ear. Reproduced from Macmillan Publishers LTD: Nature, from the study by Brand, A., Behrend, O., Marquardt, T., McAlpine, D., and Grothe, B. 2002. Precise inhibition is essential for microsecond interaural time difference coding. Nature 417, 543–547.

The first possible coding strategy can be likened to a labeled line paradigm and is derived from the Jeffress model. In this scheme a neuron will have a peak response at a particular ITD within the physiological range of ITDs. Across the population of coding neurons (i.e., MSO, NL) all spatial positions (ITDs) will be represented by different subsets of neurons according to where their peak sensitivity lies within auditory space. The second strategy depends on comparing population responses, between two broadly tuned spatial channels (McAlpine, D. *et al*., 2001; Palmer, A. R., 2004). In this scheme, information on the sound source location would depend not on the firing rate of particular neurons sensitive to small regions of space, but on a comparison of activity between the two MSOs. Each MSO neuron would respond to many positions in space, but in a graded way such that sound sources in the ipsilateral hemifield will evoke little activity while sound sources in the contralateral hemifield will evoke strong responses. Under this scheme sound source position is resolved only after a higher-order comparison of activity from the two MSOs.

The relative utility of these two coding schemes depends on the physical relationships between the stimulus frequency (wavelength) and the animal's head size. At the extremes, a low-frequency sound for an animal with a small head, the range of available IPDs is relatively small; thus broad population coding may be optimal. For higher frequencies and for animals with wide heads, there is an ample range of IPDs for which neurons could be constructed to be differentially sensitive. A recent modeling study took into account the relationships between stimulus frequency, interaural phase, and head size for four animals with different hearing ranges and head sizes (Harper, N. S. and McAlpine, D., 2004). The authors showed that across the tonotopic range for each animal, one or a combination of both coding strategies may be optimal depending on the stimulus frequency.

3.35.4 Summary and Conclusion

In both birds and mammals elegant circuitry has evolved to compute sound source location. The circuits devoted to low-frequency processing involving NL and MSO share many features designed to preserve or enhance extraction of temporal information from nVIII inputs. These include both morphological and intrinsic membrane specializations throughout the circuitry that are remarkably similar across these vertebrate classes. That being said, two systems appear to differ in several ways that are still under investigation. These include the presence or absence of delay lines, the nature of the ITD code, as well as the role of inhibitory components of each system.

A suite of studies spanning the last two decades in both birds and mammals has elucidated the importance of inhibitory circuitry for ITD processing. The mammalian studies have demonstrated that MSO neurons receive a rapid and glycinergic hyperpolarizing inhibition from auditory pathways specialized to process temporal information from each ear. In contrast, avian ITD-processing neurons in NL receive a depolarizing slow GABAergic input that is derived from an auditory center that appears not to preserve phase-locked timing information with both monaural and binaural responses. In mammals, the limited data available suggest that a temporally constrained inhibitory input is a crucial factor in setting ITD selectivity in the MSO, but at this time a well-supported model for how the inhibition imparts selectivity on these cells is lacking. In birds, the slow inhibitory input seems to be involved in both enhancing the intrinsic membrane properties of time-coding neurons and perhaps binaurally controlling the system gain. The contrasting nature of inhibition in these systems represents one of the most fundamental differences between avian and mammalian circuits for processing ITDs. A clear understanding of inhibitory function in both NL and MSO will be critical to resolving the nature of ITD encoding at these primary sites of binaural computation.

3.36.1 Introduction

A primary function of the auditory system is to determine the location of objects in the environment. Although this function is also shared by the visual and somatosensory systems, the peripheral receptors comprising these systems can encode the locations of visual and tactile objects directly via the topographic organization of the rods and cones of the retina and the mechanoreceptors of the skin, respectively. In

contrast, the hair cells of the cochlea have no mechanism to sense sound location directly, but rather encode sound frequency and intensity owing to their position along the basilar membrane and the frequency- and intensity-dependent mechanical properties of the basilar membrane itself. Thus, sound location must be computed at more central levels of the auditory system based on the neural representations of the spectral and temporal characteristics of the acoustic stimuli arriving at the two ears.

The quick and accurate determination of sound location has considerable functional significance in directing the behavior of most mammals. Some species, like bats and cats, rely heavily on localization to capture prey, while others rely on it to avoid capture. Localization also confers additional perceptual benefits, like facilitating auditory scene analysis, binaural unmasking, and increasing comprehension of speech in noisy and reverberant environments. The importance of localization was recognized early in the history of experimental psychology and physiology, and sound localization has been investigated for over 200 years. A main goal of these studies has been to determine how the direction-dependent physical parameters of sounds, or cues, arriving at the ears are used for localization. There are three primary cues to location, each of which is created by direction-dependent interactions of the incident sound waves with the head and outer ears, or pinnae:

1. interaural time differences (ITDs),
2. ILDs, and
3. monaural spectral shape cues.

Accurate localization and the associated perceptual benefits that location confers require that the cues be extracted and encoded by neurons accurately. This chapter focuses on the neural and anatomical mechanisms by which one of the cues, ILDs, is initially encoded in the auditory system. Although much of the behavioral work in sound localization has been done in human observers, we use here the cat as the model system because it is one of the only animals for which the anatomy, physiology, and psychophysics of the localization system have been well-studied and for which there is a good understanding of the acoustical cues to sound location available to them.

3.36.1.1 The Duplex Theory of Sound Localization

Psychophysical studies in humans have endeavored to discover how the ITD, ILD, and spectral cues are used for the perception of location. At present, the consensus on what the cues are and how they are used is strongest for the case of sources varying in azimuth along the horizontal plane. Psychophysical experiments in this area have consistently revealed that low- and high-frequency tones can be accurately localized by both humans and cats, but that midfrequency tones (1.5–3.0 kHz in humans, slightly higher frequencies in cats) cannot. The presence of such discontinuities in the function relating localization accuracy to tone frequency is suggestive of separate physiological mechanisms that mediate, in this case, the localization of high- and low-frequency sources, respectively. The poor performance for the midfrequency tones presumably reflects the transition from using one cue and/or mechanism to another, the cues being ITDs and ILDs. Based on the behavioral and acoustic evidence, a dual mechanism for localization, the so-called duplex theory, was proposed whereby low-frequency sounds are localized based on the ITD cues while higher-frequency sounds are localized based on the ILD cue (Rayleigh, L. J. S., 1907; Stevens, S. and Newman, E., 1936; Mills, A. W., 1958; Casseday, J. H. and Neff, W. D., 1973).

3.36.1.2 The Superior Olivary Complex

While the duplex theory has served as the principal model of localization in azimuth for over a century, the exact mechanisms by which each of the localization cues are first encoded and then ultimately integrated in the responses of auditory neurons are not known in detail. Early anatomical studies revealed that the first places in the auditory pathway to receive large-scale and systematic converging inputs from both ears were two of the primary nuclei comprising the superior olivary complex (SOC, Figure 1), the medial superior olive (MSO, not shown in Figure 1) and the LSO.

Later, physiological studies found that the neurons in the MSO and LSO were, in general, separately sensitive to ITDs and ILDs, respectively. And lesion studies showed that sectioning the afferent inputs to the SOC (Masterton, B. *et al.*, 1967) or lesioning the SOC (Kavanagh, G. L. and Kelly, J. B., 1992) dramatically decreases the ability of experimental animals to localize sounds in the horizontal plane suggesting that the SOC nuclei are necessary for localization. The anatomical, physiological, and psychophysical evidence suggests that at this very early stage, the MSO and the LSO provide the anatomical and physiological bases for the duplex theory.

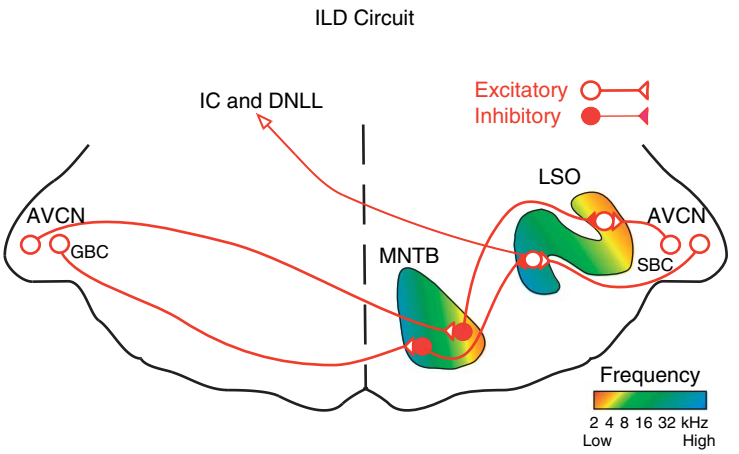

Figure 1 Illustration of a frontal section through the cat brainstem showing the ascending pathways through the lateral superior olive (LSO), which is believed to be responsible for encoding interaural level differences (ILDs). LSO neurons receive bilateral inputs from both ears. The input from the ipsilateral ear via the spherical bushy cells (SBCs) is excitatory (open symbols) but the input from the contralateral ear via the globular bushy cells (GBCs) of the contralateral anteroventral cochlear nucleus (AVCN) is inhibitory (filled symbols) due to the additional synapse in the ipsilateral medial nucleus of the trapezoid body (MNTB). The ipsilateral excitation and contralateral inhibition allows LSO neurons to encode ILDs. LSO neurons send excitatory projections to the contralateral inferior colliculus (IC) and dorsal nucleus of the lateral lemniscus (DNLL) and inhibitory projections (not shown) to the ipsilateral IC and DNLL. The color bar and shading indicates the tonotopic organization and shows that the neurons comprising the MNTB and LSO are sensitive to predominantly high-frequency sounds. The SBCs and GBCs receive excitatory input from the auditory nerve (not shown).

The hypothesis that ILDs are first encoded in the LSO is examined here. (Review of the mechanisms for ITD and spectral cue coding can be found elsewhere in this volume.) The LSO ILD-coding hypothesis was founded upon two classical observations. First, the LSO is one of the most peripheral nuclei receiving massive convergence of inputs from the two ears. Second, the LSO neurons respond systematically to ILDs of stimuli presented to the two ears. Since these initial observations, strong support for this hypothesis has come from disparate scientific fields, which we cover here. First, the ILD as an acoustical cue to location will be considered. Second, we will examine the anatomical, biophysical and physiological characteristics of the neurons comprising the LSO circuit (Figure 1) that are responsible for ILD coding. Finally, we consider comparative studies that have examined the functional roles of the SOC nuclei through combined anatomical, physiological, and psychophysical observations.

3.36.2 The Three Main Acoustical Cues to Sound Source Location

The task of localizing a sound's source differs from localization by the other spatial senses because the physical cues for location are different. The cues for sound localization are generated by the interaction of the sound waves with the anatomical structures supporting the receptors of the ear, namely the head and pinnae, and not by the topographic organization of the receptors themselves. Therefore, in order to understand the neural mechanisms for localization based on ILDs, the acoustical basis for the ILD cue and how the cue varies with sound location must be considered.

The three primary cues to location are illustrated in Figure 2 for an adult cat (acoustical recordings from Tollin, D. J., 2004). The cues are measured by placing small probe tube microphones deep inside the ear canal near the tympanic membranes of both ears. A sound with known spectral and temporal characteristics is delivered from a loudspeaker (Figure 2(a)) and the acoustical responses that result are recorded by the microphones. This process is repeated as the loudspeaker is systematically placed at various locations around the subject.

Consider the cues available to a cat for a broadband transient sound (i.e., a click) delivered from just one location (−40°, 0°, Figure 2(a)). Figure 2(b) shows the averaged acoustical responses recorded at the left and right ears to multiple clicks presented from this location. For each location (i.e., our example location), the acoustic transfer function is

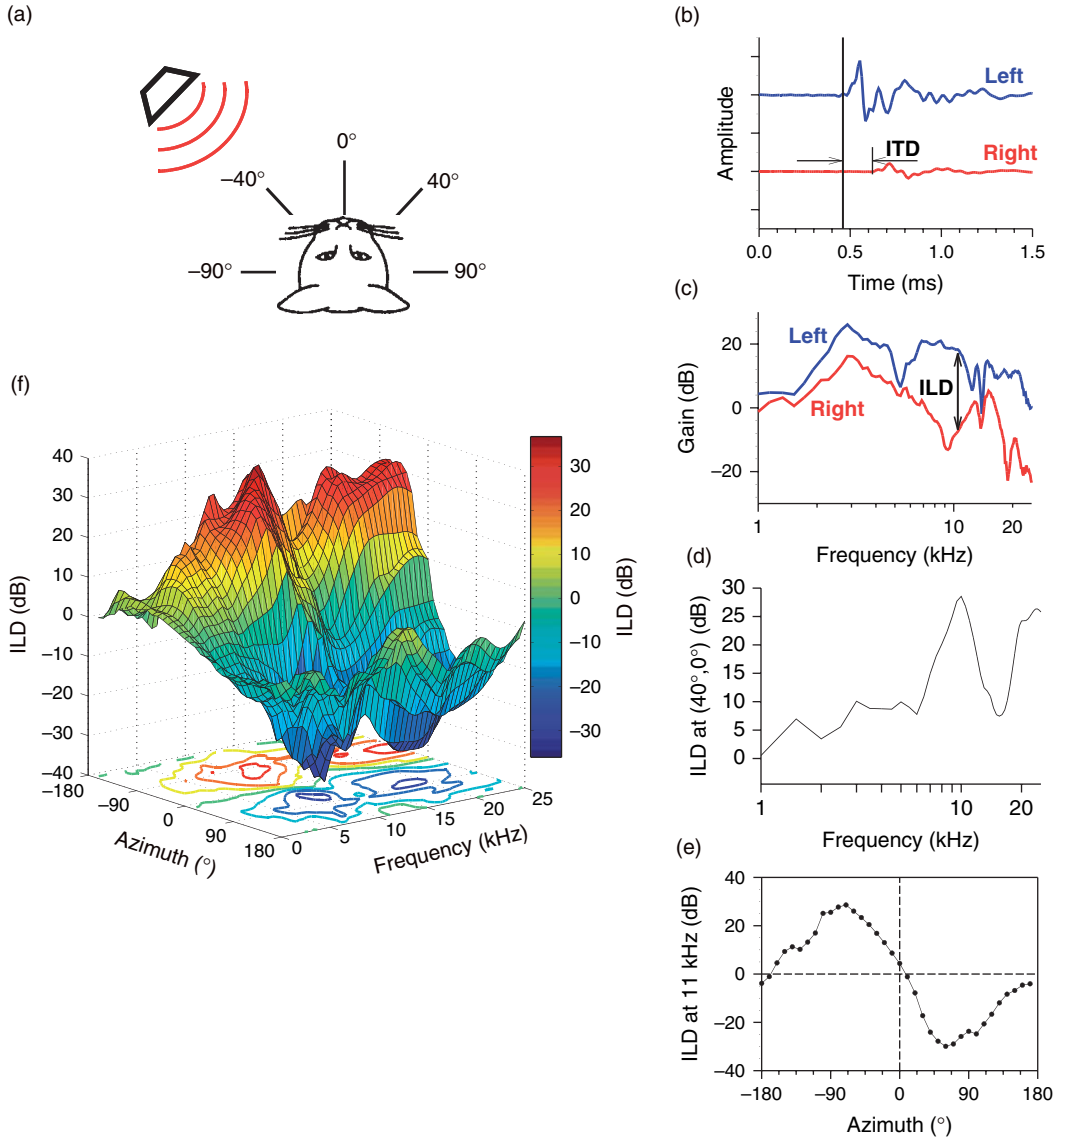

Figure 2 The acoustical cues to sound location in the cat. (a) Broadband clicks are presented repeatedly from a loudspeaker at −40°, 0°. (b) Averaged acoustical responses recorded by microphones near the eardrums in the left and right ears to the clicks presented from −40°, 0°. The interaural time difference (ITD) cue is represented by the relative differences in the onset times of the impulse responses at each ear. (c) The head-related transfer functions (HRTFs) plot the spectrum of the acoustical responses in (b) in terms of the acoustical gain introduced by the presence of the head and pinnae relative to the sound level in response to the click recorded in the absence of the cat. The monaural spectral cues are captured by the changes in the shapes of the spectra as a function of source location. (d) The interaural level difference (ILD) cue is indicated by the relative differences in the gains of the HRTFs as a function of frequency as shown in (c) for a source at −40°, 0°. The ILDs were computed by taking the difference of the left and right ear HRTFs after filtering them though a bank of 1/6-octave Gaussian filters with different center frequencies. (e) At any one frequency, ILDs vary systematically with source azimuth. Frequency is 11 kHz in the example. (f) The joint spatial and frequency dependence of ILDs. ILDs are a complicated function of azimuth and frequency for high stimulus frequencies. For illustrative purposes, sources were restricted to the horizontal plane and only in the frontal hemisphere for frequencies between 1 and 30 kHz. The HRTFs and ILDs were derived directly from the acoustical measurements of Tollin D. J. (2004).

computed by removing from the left and right ear recordings the response recorded at the microphones but in the absence of the cat. This correction procedure effectively removes the stimulus, loudspeaker, and microphone frequency responses leaving only the response due to the torso, head, and pinnae. Figure 2(b) shows the corrected responses, commonly called the impulse responses. Figure 2(c)

shows the Fourier transform of the impulse responses, called head-related transfer functions (HRTFs), for the (−40°, 0°) location; the HRTFs are plotted in terms of the acoustical gain resulting from the head and pinnae relative to the sound level in response to the click in the absence of the cat. A left and right ear pair of HRTFs for any given location captures the frequency- and direction-dependent changes to the acoustic stimulus from that location due to interactions of the incident sound waves with the head, pinnae, and torso.

3.36.2.1 Interaural Time Differences

The ITD and ILD cues are readily apparent in the differences between the impulse responses (Figure 2(b)) and the spectra (Figure 2(c)) of the HRTFs. These binaural cues result because the ears are physically separated in space by the head, which is also acoustically opaque. Direction-dependent differences in path lengths that sound must travel to reach each ear give rise to the ITD cue. In the cat, ITDs increase monotonically with azimuth along the horizontal plane up to a maximum of 300–400 μs (Roth, G. L. *et al*, 1980). The range of ITDs is directly proportional to head diameter so species with larger heads exhibit a larger range of ITDs (Masterton, B. and Diamond, I. T., 1973). For example, the maximum ITD in humans can exceed ∼700 μs. Yet some species of bats and rodents, which have head diameters <1 cm, can have maximum ITDs as small as 40 μs. While such small ITDs are likely to be of little use for localization, substantial ILD cues that can be used for localization will be available at high frequencies.

3.36.2.2 Interaural Level Differences

The ILD cue results from frequency-dependent modifications of the incident sound pressure waves made by the head and pinnae and is defined as the difference in sound pressure level of the signals arriving at the two ears as a function of sound frequency (e.g., Figure 2(c)). ILDs result in part from an acoustic shadow effect that occurs for sounds whose wavelengths are shorter than the diameter of the head so that they are reflected off the head. As a result, relative to the sound level at the ear ipsilateral (same side) to the source, the head effectively attenuates the sound arriving at the contralateral (opposite side) ear. Two main factors contribute to ILDs, both of which can be seen in the sound spectra at the ears (Figure 2(c)). First, there is a general boosting of sound level by the ipsilateral pinna, as evidenced by gains >0 dB. (The gains at ∼3 kHz are due to the ear canal resonance.) Second, the shadowing effect attenuates sounds at the contralateral ear resulting in smaller gains at every frequency than the gains at the ipsilateral ear (Figure 2(c)). Measurements in adult cats confirm the observations made in Figure 2 (Wiener, F. M. *et al*., 1966; Phillips, D. P. *et al*., 1982; Calford, M. B. and Pettigrew, J. D. 1984; Irvine, D. R., 1987). Although the amplification provided by the ipsilateral pinna can approach 20–25 dB sound pressure level (SPL) at some frequencies (Phillips, D. P. *et al*., 1982; Musicant, A. D. *et al*., 1990), for most frequencies, the acoustic head shadow accounts for much of the magnitude of the ILD (Irvine, D. R., 1987).

The ILD cue varies systematically with location in cats (Wiener, F. M. *et al*., 1966; Moore, D. R. and Irvine, D. R., 1979; Phillips, D. P. *et al*., 1982; Calford, M. B. and Pettigrew, J. D., 1984; Irvine, D. R., 1987; Martin, R. L. and Webster, W. R., 1989; Musicant, A. D. *et al*., 1990; Rice, J. J. *et al*., 1992; Tollin, D. J., 2004). However, at any one location, the ILD also varies with frequency. The example in Figure 2 illustrates the dual nature of this complexity. First, the frequency-dependent ILD for the source at (−40°, 0°) is given by the difference in the gains at the two ears (Figure 2(c)), which is plotted in Figure 2(d) as a function of frequency. Second, Figure 2(e) shows how the ILD at one frequency (11 kHz) varies with azimuth. Finally, to illustrate the joint direction- and frequency-dependent patterns of ILD, Figure 2(f) shows ILDs as a function of azimuth and frequency for sources along the horizontal plane. Three main points are apparent. First, at each azimuth, the ILD–frequency functions (e.g., Figure 2(d)) are nonmonotonic and exhibit complex shapes. As expected from physical acoustics, ILDs are small for low frequencies and systematically increase in magnitude for frequencies approaching ∼10 kHz. Frequencies >∼10 kHz have wavelengths that are on the order of the dimensions of the pinnae, so the pinnae begin to contribute in complex ways to ILDs at these higher frequencies. Second, for frequencies <∼10 kHz, the ILD–azimuth functions are nearly sinusoidal (Figure 2(e); and sigmoidally shaped for sources between ±90°), and the rate of change of ILD with azimuth near the midline increases with frequency. Third, for frequencies >10 kHz, the ILD–azimuth functions are highly nonmonotonic and exhibit peaks and dips. In general, the nonmonotonicity of the ILD–azimuth functions (a pattern also

present in measurements of human ILDs) creates problems for the use of this cue in any single frequency band to represent azimuthal location unambiguously (see Martin, R. L. and Webster, W. R., 1989). However, the *pattern* of ILD across frequency for any one location (e.g., Figure 2(d) for the source at (−40°, 0°)) might be used to resolve the ambiguity.

3.36.2.3 Monaural Spectral Shape Cues

Monaural spectral shape cues arise from direction- and frequency-dependent reflection and diffraction of the pressure waveforms of sounds by the head, torso, and pinna that result in broadband spectral patterns, or shapes, that change with location. Prominent direction-dependent features in the spectra, such as the deep notches that occur at some locations (e.g., 5.5 and 9.5 kHz for the left and right ear, respectively, in Figure 2(c)), are thought to be critical both for localization in elevation, where the binaural cues change little with variations in elevation, as well as facilitating the distinction between sources in front of an observer from sources behind. These spectral features are believed to be initially extracted by the principal neurons of the dorsal cochlear nucleus (CN).

3.36.3 Interaural Level Differences Are Initially Processed in the Lateral Superior Olive

For ILDs to be useful for localization there must be neural mechanisms to encode them. It is easy to imagine a group of neurons where the neural representation of sound level at one ear is simply subtracted from the representation of sound level at the other ear. Insofar as the inputs to this hypothetical mechanism represent the sound levels accurately, this neural differencer could produce a neural correlate of the acoustical ILD cue.

Research has suggested that a correlate of ILD is encoded by the discharge rates of LSO neurons. ILD sensitivity results because LSO neurons are inhibited by sounds presented to the contralateral ear and excited by sounds presented to the ipsilateral ear (Boudreau, J. C. and Tsuchitani, C., 1968). The inhibition can be thought of as the neural equivalent of subtraction. Many neurons in higher auditory nuclei, including the dorsal nucleus of the lateral lemniscus (DNLL), inferior colliculus (IC), medial geniculate body, and auditory cortical areas, are sensitive to changes in sound location, usually for sounds in the contralateral hemifield (Irvine, D. R. F., 1986). These neurons likely derive that sensitivity in large part from the initial processing in LSO neurons, which, as indicated in Figure 1, project excitatory afferents to the contralateral DNLL and IC and inhibitory afferents (not shown) to the ipsilateral IC and DNLL (Glendenning, K. K. and Masterton, R. B., 1983; Glendenning, K. K. *et al.*, 1992; Loftus, W. C. *et al.*, 2004). The initial processing of ILDs by the LSO may place limitations on the spatial selectivity exhibited in higher-order nuclei and, thus, might ultimately limit behavioral sound localization performance. For this reason, we restrict our review of ILD processing to the LSO.

It has been long hypothesized that the functional role of the LSO is to extract and represent the ILD cue as a function of frequency (Tollin, D. J., 2003). But what does ILD processing entail? We review here the anatomical, biophysical, and physiological specializations of the LSO and its afferents (Figure 1) that are necessary for the accurate encoding of ILD.

3.36.3.1 Lateral Superior Olive Neurons Receive Excitatory Inputs from One Ear and Inhibitory Inputs from the Other Ear

Figure 1 summarizes the major afferent inputs from the two ears to the LSO. The principal neurons of the LSO receive excitatory inputs from the ipsilateral ear through the spherical bushy cells (SBCs) of the ipsilateral anteroventral cochlear nucleus (AVCN) (Stotler, W. A., 1953; Warr, W. B., 1966; Osen, K. K., 1969; Warr, W. B., 1972; Tolbert, L. P. *et al.*, 1982; Glendenning, K. K. *et al.*, 1985; Shneiderman, A. and Henkel, C. K., 1985; Cant, N. B. and Casseday, J. H., 1986; Saint Marie, R. L. *et al.*, 1989; Smith, P. H. *et al.*, 1993). LSO neurons receive inhibitory afferents from the contralateral ear via neurons in the ipsilateral medial nucleus of the trapezoid body (MNTB) (Harrison, J. M. and Warr, W. B., 1962; 1972; Elverland, H. H., 1978; Tolbert, L. P. *et al.*, 1982; Glendenning, K. K. *et al.*, 1985; Spangle, K. M. *et al.*, 1985; Friauf, E. and Ostwald, J., 1988; Bledsoe, S. C. *et al.*, 1990; Smith, P. H. *et al.*, 1991; Banks, M. I. and Smith, P. H., 1992; Smith, P. H. *et al.*, 1998) which in turn receive excitatory input from the globular bushy cells (GBCs) of the contralateral AVCN (Harrison, J. M. and Warr, W. B., 1962; Warr, W. B., 1972; Tolber, L. P. *et al.*, 1982; Glendenning, K. K. *et al.*, 1985; Smith, P. H. *et al.*, 1991). The SBCs and GBCs receive a

direct excitatory input from the auditory nerve (not shown in Figure 1).

The hypothesis that the LSO detects differences in the strengths of synaptic inputs received from each ear was first inferred from the patterns of neural discharges elicited when presented with acoustic stimuli containing ILDs (Boudreau, J. C. and Tsuchitani, C., 1968). The early studies found that ipsilateral sound-evoked discharges could be systematically reduced by increasing the level of the stimuli presented to the contralateral ear. Although this hypothesis was attractive, a change in discharge rate with ILD does not by itself directly implicate the LSO as the actual site where ILD is computed. The actual computation could have occurred more peripherally.

Moore M. J. and Caspary D. M. (1983) provided the first conclusive evidence that ILD sensitivity results directly from the nature of the synaptic inputs on LSO neurons. These experiments showed that the input from the ipsilateral MNTB was glycinergic and inhibitory. Inhibition that was evoked by an acoustic stimulus at the contralateral ear was blocked by iontophoretic application of the glycine receptor antagonist, strychnine. Moreover, an inhibitory effect comparable to that evoked by acoustic stimulation could also be elicited by iontophoretic application of glycine. Immunocytochemical studies have since confirmed that the principal neurons of the MNTB are glycinergic (Wenthold, R. J. *et al.*, 1987; Glendenning, K. K. and Baker, B. N., 1988; Helfert, R. H. *et al.*, 1989; Saint Marie, R. L. *et al.*, 1989; Adams, J. C. and Mugnaini, E., 1990; Bledsoe, S. C. *et al.*, 1990; Henkel, C. K. and Brunso-Bechtold, J. K., 1995) and that glycine receptors are abundantly expressed on the principal neurons of the LSO (Sanes, D. H. *et al.*, 1987; Glendenning, K. K. *et al.*, 1991; Korada, S. and Schwartz, I. R., 1999).

Intracellular recordings *in vivo* from single LSO neurons show that acoustic stimulation of the ipsilateral and contralateral ears generates excitatory (EPSPs) and inhibitory (IPSPs) postsynaptic potentials, respectively (Finlayson, P. G. and Caspary, D. M., 1989). Moreover, *in vitro* recordings, which allow the afferent pathways to LSO from each ear to be electrically stimulated directly and independently, also showed that ipsilateral inputs generated glutamatergic EPSPs while contralateral inputs generated glycinergic IPSPs, although there were exceptions (Caspary, D. M. and Faingold, C. L., 1989; Sanes, D. H., 1990; Wu, S. H. and Kelly, J. B., 1991; 1992). For example, some LSO neurons could be inhibited by ipsilateral electrical stimulation from glycinergic inputs directly to LSO neurons themselves, although the source of this input is not clear (Wu, S. H. and Kelly, J. B., 1991; 1994). Such inputs were also inferred from *in vivo* studies, where some LSO neurons could be inhibited by ipsilateral presentation of tones with frequencies away from the characteristic frequency (CF) consistent with side-band inhibition (Brownell, W. E. *et al.*, 1979; Caird, D. and Klinke, R., 1983). Sideband inhibition could play a role in sharpening the frequency tuning of the ipsilateral input.

3.36.3.2 Inputs Encode the Spectral and Temporal Characteristics of the Sounds at Each Ear

3.36.3.2.1 Spectral representation by lateral superior olive afferents

A hypothesized role of the LSO is to compute a correlate of the ILD across frequency for any one location (e.g., Figure 2(d)). For this to take place, the afferent inputs to the LSO must accurately encode the broadband spectral characteristics of the sounds at each ear (e.g., Figure 2(c)). Clearly, the population of auditory nerve fibers (ANFs) must initially encode sound spectra sufficiently for the computation of ILDs. This representation must be preserved in the pathways to the LSO through the bushy cells and the MNTB neurons. At the periphery, ANFs display narrow frequency selectivities, evidenced by sharp frequency tuning curves (Kiang, N. Y. S. *et al.*, 1965). Therefore, the broadband spectrum of high-frequency stimuli is likely represented via the pattern of discharge rates across the population of ANFs, with the spectral level at each frequency being proportionally represented by the discharge rate of ANFs with that CF (Pfeiffer, R. R. and Kim, D. O., 1975). ANFs project to the CN, which is tonotopically organized (Rose, J. E. *et al.*, 1959), so the representation of the spectrum by the ANF array will be available to the CN, including the bushy cells of the AVCN.

Several studies have examined the ability of the ANF population to represent the spectral shapes of HRTFs themselves (e.g., Figure 2(c)). These studies recorded the responses from populations of cat ANFs, spanning a broad range of CFs, to broadband noise stimuli that had been filtered by HRTFs measured from adult cats. An early study suggested that single ANFs could encode the spatial location-dependent spectral features of HRTFs via their discharge rates (Poon, P. W. and Brugge, J. F., 1993).

However, another concluded that the most salient spectral characteristics, such as the deep spectral notches, could not be accurately encoded (Rice, J. J. *et al.*, 1995). Rice J. J. *et al.* (1995) used a limited set of HRTF measurements, so it is not clear from that study whether the ANF population could encode the more global spectral characteristics necessary for the computation of ILD independent of the sharp notches. This possibility was reexamined with a computational model (May, B. J. and Huang, A. Y., 1997). By simulating the responses of a larger population of ANFs, May B. J. and Huang A. Y. revealed that the discharge rates represented across the ANF population contained information that was sufficient to account for the behavioral measurements of sound localization acuity by cats for the high-frequency sounds where ILD cues predominate (Martin, R. L. and Webster, W. R., 1989).

Less is known about the spectral-encoding capabilities of bushy cells and MNTB neurons, which provide the inputs to LSO, since studies similar to those described above have not yet been performed. However, SBCs (Rhode, W. S. and Smith, P. H., 1986; Spirou, G. A. *et al.*, 1990; Smith, P. H. *et al.*, 1993) and MNTB neurons (Guinan, J. J., Jr. *et al.*, 1972a; Tsuchitani, C., 1997; Smith, P. H. *et al.*, 1998; Kopp-Scheinpflug, C. *et al.*, 2003) have physiological response characteristics that are nearly identical to their ANF or GBC inputs, respectively: narrow frequency tuning, primary-like or primary-like with notch responses to tone pips at CF; similar dynamic ranges, etc. Based on this similarity, it is possible that the ANF rate representation of the spectrum is preserved through the SBCs and GBCs as well as the MNTB.

3.36.3.2.2 Temporal representation by lateral superior olive afferents

Many natural sounds, like speech and animal vocalizations, are modulated over time in both frequency and amplitude. Other sounds are brief and transient, like rustling leaves and snapping twigs. To compute the ILD present in these signals at the LSO requires special care because the inputs from the two ears must encode the temporal variations in the spectra with high fidelity. Surprisingly, the neurons comprising the ascending pathway through the LSO (Figure 1) contain remarkable anatomical and biophysiological specializations that appear suited to accurate encoding of temporal information. This is particularly interesting because it is contrary to the hypothesis that the ILD pathway is concerned only with the encoding of sound spectra.

The ANF synapses onto the bushy cells of the CN (Brawer, J. R. and Morest, D. K., 1975; Cant, N. B. and Morest, D. K., 1979; Smith, P. H. and Rhode, W. S., 1987) along with the intrinsic biophysical properties of the bushy cells themselves (Trussel, L. O., 2002) are specialized to permit the accurate preservation of temporal information. Consistent with these biophysical specializations, the encoding of temporal variations in the fine structure of low-frequency sounds is enhanced over that of their ANF input (Joris, P. X. *et al.*, 1994). Yet at high frequencies where ILDs are useful, ANFs do not encode temporal fine structure (Johnson, D. H., 1980), but they can encode the amplitude (AM) (Figure 4) (Joris, P. X. and Yin, T. C. T., 1992) and frequency (FM) modulations of the stimuli (Britt, R. and Starr, A., 1976). The representations of AM and FM stimuli are preserved in the bushy cells and MNTB neurons (e.g., Figure 4) (Moller, A. R., 1974; Rhode, W. S. and Smith, P. H., 1986; Rhode, W. S. and Greenberg, S., 1994; Joris, P. X. and Yin, T. C. T., 1998). MNTB neurons have similar membrane properties as bushy cells, with short membrane time constants and nonlinear current–voltage relationships (Wu, S. H. and Kelly, J. B., 1991; Banks, M. I. and Smith, P. H., 1992), also making them well suited to preserve temporal information. Indeed, low-CF MNTB neurons exhibit phase locking that is enhanced over similar CF ANFs (Tollin, D. J. and Yin, T. C.T., 2005). Together, these specializations ensure that rapidly time-varying changes in the amplitude and frequency content of stimuli at each ear are accurately represented through the pathway to the LSO neurons.

3.36.3.3 The Inputs from Each Ear to Individual Neurons Have Similar Frequency Tuning

In order for the LSO to compute a faithful correlate of the ILD, the afferents to individual LSO neurons must encode corresponding frequency regions of the spectrum. Like the CN, the LSO exhibits a tonotopic organization with neurons responding to high frequencies located in the ventromedial limb and neurons responding to lower frequencies represented in the dorsolateral limb (see shading in Figure 1). The representation of frequency is skewed such that most LSO neurons respond to frequencies $>\sim$2 kHz (Tsuchitani, C. and Boudreau, J. C., 1966; Guinan, J. J., Jr. *et al.*, 1972b; Tsuchitani, C., 1977). A similar

and parallel disproportionate representation of high frequencies exists in the MNTB (e.g., Figure 1; Guinan, J. J., Jr. *et al.*, 1972b). There is evidence that the frequency selectivity of GBCs is also skewed towards high frequencies (Smith, P. H. *et al.*, 1991). The parallel overrepresentation of high-frequency-selective neurons in GBCs, the MNTB, and the LSO correlates well with the acoustical measurements in cats showing that the ILD cue becomes prominent only for frequencies above ~2–3 kHz (e.g., Figure 2(f)).

There is strong anatomical and physiological support for matched-frequency inputs to LSO. First, anatomically, the tonotopic organization of LSO determined from physiological studies matches the topography of the afferent projections to the LSO from the ipsilateral CN (Warr, W. B., 1966) and from the ipsilateral MNTB (Elverland, H. H., 1978; Glendenning, K. K. *et al.*, 1985; Spangler, K. M. *et al.*, 1985; Smith, P. H. *et al.*, 1998). Second, frequency tuning curves for the contralateral inhibitory ear have been measured by determining the sound level of tones presented to the contralateral ear, at different frequencies, that just inhibited a set percentage of the discharges evoked by a fixed-level CF tone presented to the ipsilateral ear (Figure 3(a)).

The inhibitory frequency tuning curves that result (black lines, Figure 3(b)) were similar in shape and yielded nearly identical estimates of the CF as the ipsilateral excitatory tuning curves (red dashed line, Figure 3(b) (Boudreau, J. C. and Tsuchitani, C., 1968; Caird, D. and Klinke, R., 1983; Tsuchitani, C., 1997). That is, the lowest intensity of contralateral stimulation that can evoke inhibition occurs when the frequencies of the tones presented to the two ears are matched at the CF (11 kHz in the example). However, as is apparent in Figure 3(b) there was a tendency for the bandwidths of the frequency tuning estimated from the inhibitory input to be wider than those of the ipsilateral excitatory tuning curves. Because the tuning curves of MNTB neurons of similar CFs have been found to be narrower than the inhibitory tuning curves of LSO neurons, there is likely a convergence of inhibitory MNTB

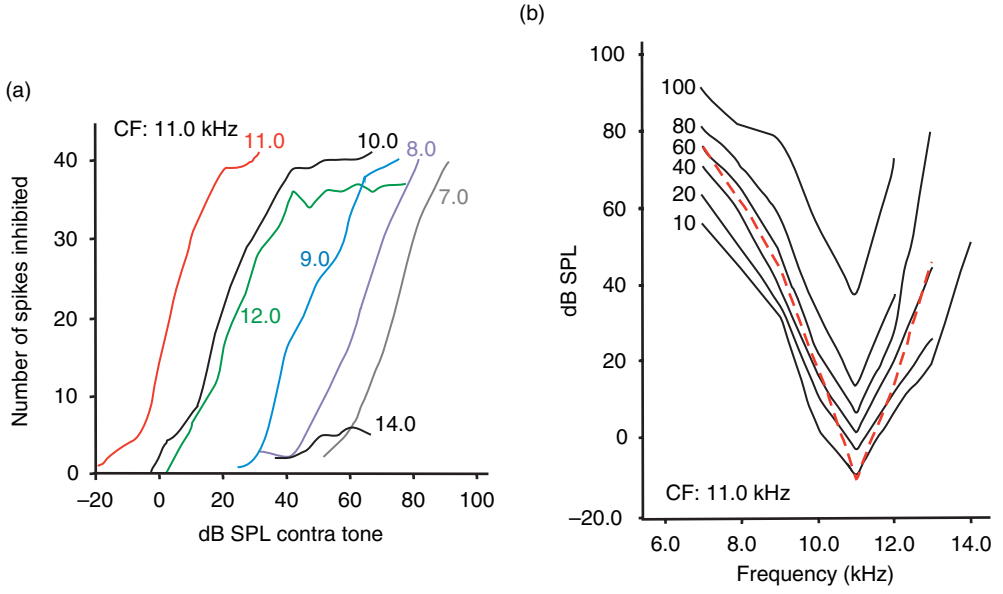

Figure 3 Frequency selectivity of the contralateral inhibitory and ipsilateral excitatory input to lateral superior olive (LSO) neurons is matched. (a) The number of spikes by which the response to a tone presented at the neuron's characteristic frequency (CF, 11.0 kHz) to the ipsilateral ear was reduced or inhibited by the simultaneous presentation to the contralateral ear of tones with different frequencies (indicated by colored lines and associated numbers) and at different sound levels (abscissa). Spikes are inhibited at the lowest sound levels when the tones presented to the two ears were matched at the CF (red line). (b) Inhibitory threshold tuning curves calculated from the functions plotted in (a). The shape of the frequency threshold curve for the excitatory ear (dashed red line) is well matched by the inhibitory tuning curves (black lines). Each inhibitory tuning curve represents the sound levels and frequencies at which equal inhibitory effects were found in (a). Inhibitory effects are expressed as the percentage of inhibition relative to the ipsi-only stimulus (values next to each curve). Reprinted with permission from Boudreau, J. C. and Tsuchitani, C. 1968. Binaural interaction in the cat superior olive S segment. J. Neurophysiol. 31, 442–454.

inputs with slightly different CFs onto LSO neurons (Boudreau, J. C. and Tsuchitani, C., 1968; Sanes, D. H. and Rubel, E. W., 1988; Tsuchitani, C., 1997).

3.36.3.4 Inputs from the Two Ears Reach Lateral Superior Olive Neurons in Approximate Temporal Register

If the peripheral representations of sounds that are brief or have rapid AM and/or FM do not arrive at the LSO in approximate temporal register, then the computation of the ILD in those stimuli will be compromised. This ILD-timing problem has been illustrated nicely by Joris P. X. and Yin T. C. T. (1995), which is reprinted in Figure 4.

The illustration shows hypothetical responses to an AM tone by the constituent neurons in the ILD pathway (Figure 1). In Figure 4(a), three periods of the AM waveform are shown as arriving at the ears with zero time delay, or zero interaural phase difference in the envelopes, which approximates a sound source at the midline. The temporal fluctuations in the amplitude of the stimulus are conveyed in the timing of the discharges of the ANFs, bushy cells, and the MNTB neuron. In this example, for the LSO to compute the correct acoustic ILD, which is 0 dB because the source is at the midline, the inputs from the ipsilateral SBC and the ipsilateral MNTB neuron must arrive at the LSO neuron simultaneously. For the ideal case in Figure 4(a) where the inputs have been forced to arrive in register, the LSO neuron's response is minimal when the ILD of the stimulus is 0 dB.

If at any point along the pathway from the sound source to the synaptic inputs to the LSO there are additional time delays, then the inputs will not arrive in register. And because the magnitude of the responses of the inputs fluctuates in time, there will be a corresponding change in the relative levels of excitation and inhibition at the LSO neuron. The functional consequences of temporal delays on ILD coding are illustrated in Figure 4(b) in which the neural input from the contralateral ear is delayed and arrives at the LSO later than the ipsilateral input. The ILD of the stimuli remains 0 dB. In this hypothetical case, the delay is imposed on the acoustical stimuli themselves, but in principle a comparable delay could result at any point in the LSO circuit (Figure 1). Due to the delay, the excitatory and inhibitory representations of the AM waveforms at the inputs to LSO are not in register. Consequently, relative to the zero-delay condition (Figure 4(a)) there is a release from inhibition leading to a large increase in the discharge rate of the LSO neuron. Clearly the encoding of the ILDs in such stimuli via the discharge rate of LSO neurons can be confounded by delays at any point in the circuit.

There are at least three ways in which the contralateral input is delayed relative to the ipsilateral. First, the neural path to the LSO is ~5.5–7.0 mm (in the cat; Tsuchitani, C. and Johnson, D. H., 1991) longer from the contralateral ear than the ipsilateral ear. Assuming that the axons of all neurons had equal diameters (and thus, equal conduction velocities), the contralateral input to LSO would arrive ~0.26–0.33 ms after the ipsilateral input (Tsuchitani, C. and Johnson, H., 1991). Second, the additional synapse through the MNTB adds an additional delay of ~0.5 ms (Smith, P. H. *et al.*, 1998). Finally, the sound source may not be equidistant from the two ears generating a delay due to the ITD of maximally ~0.4 ms (Roth, G. L. *et al.*, 1980). Even without the ITD, the neural circuitry could theoretically impose a delay on the contralateral input to LSO of nearly 1.0 ms. As illustrated in Figure 4, the consequences of such delays on ILD processing can be great.

Fortunately, there are at least three anatomical specializations along the contralateral pathway that work in concert to compensate for the delay brought about by the added path length and extra synapse in the contralateral ear input. First, the axonal diameters of the GBCs, which provide the input to the contralateral MNTB, are about three times larger and MNTB axons two times larger than the axons from the SBCs that provide the excitatory input from the ipsilateral CN (Brownell, W. E., 1975; Spangler, K. M. *et al.*, 1985). Thus, conduction times through axons are relatively shorter in the contralateral than in the ipsilateral circuit. Second, although the MNTB has traditionally been thought of as just a relay nucleus whose sole purpose is to invert the sign of the synaptic input to the LSO from the contralateral CN from excitatory to inhibitory, the GBC/MNTB synapse may have further functions (e.g., Kopp-Scheinpflug, C. *et al.*, 2003). The input from contralateral GBCs onto MNTB neurons forms one of the largest and most secure synapses in the whole CNS, referred to as the calyx of Held (Morest, D. K., 1973). Each MNTB principal neuron receives only a single calyx from a GBC, which envelops about half of the available surface of the soma, and large presynaptic terminals that produce large postsynaptic currents (Banks, M. I. and Smith, P. H., 1992; Smith, P. H. *et al.*, 1998). MNTB neurons have short time constants, receptors with fast kinetics, and specialized ion channels that together

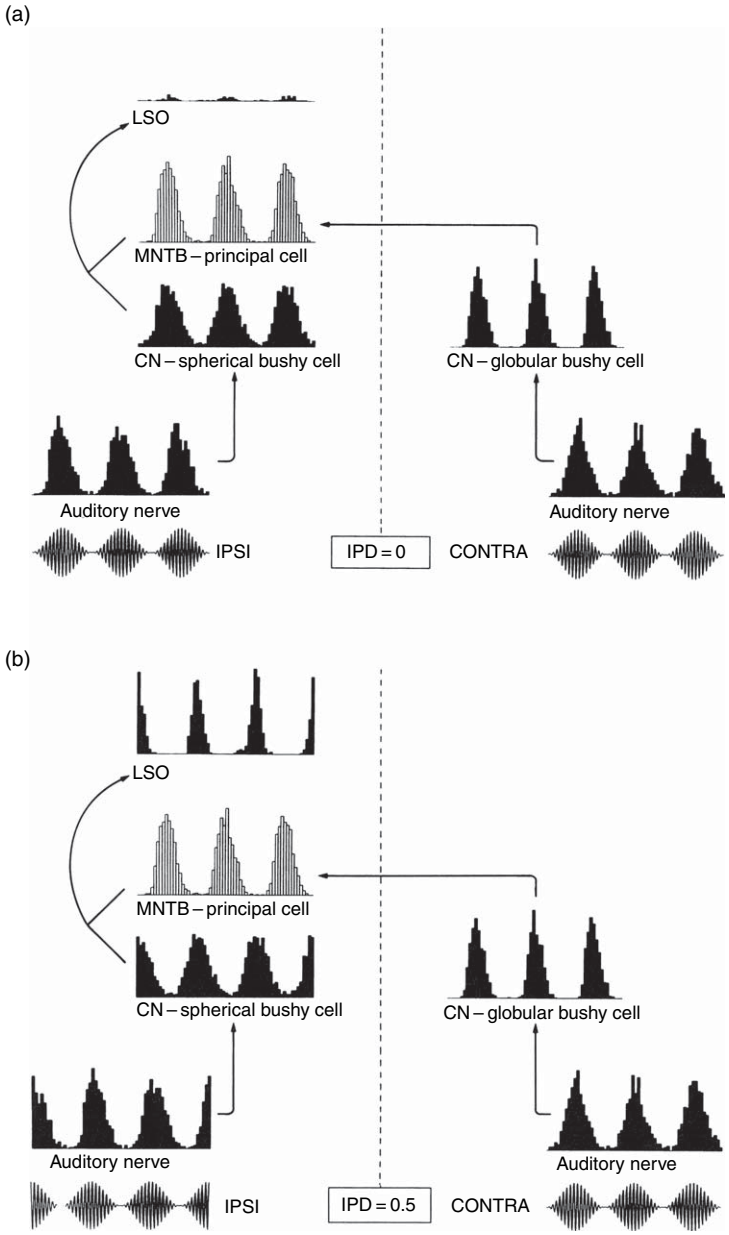

Figure 4 Illustration of the effect on interaural level difference (ILD) coding of delayed contralateral inhibition. (a) Hypothetical responses of a lateral superior olive (LSO) neuron and its afferents (e.g., Figure 1) to an amplitude-modulated (AM) stimuli presented in phase (0 time delay) to the two ears with an ILD of 0 dB plotted as poststimulus time histograms. The afferents encode the ongoing amplitude modulations of the stimuli. In the example, the excitatory and inhibitory representations arrive at the LSO neuron in temporal register resulting in a small discharge rate for this stimulus with an ILD of 0 dB. (b) Hypothetical responses of the same LSO neuron and its afferents to the AM stimuli that still has an ILD of 0 dB but contralateral stimulus has been delays in time (equivalent to an IPD in the envelopes of 0.5). The time delay is preserved by the responses of the contralateral afferents. Consequently, the excitation and inhibition do not arrive in temporal register and there is an effective release from inhibition resulting in an increased discharge rate of the LSO neuron relative to that in (a). Even though the ILDs of the stimuli in (a) and (b) were identical, the LSO response was not the same due to the relative delay between the excitation and inhibition. The delay in the example was imposed on the acoustic stimuli themselves, but a similar effect could occur by imposing a delay at any point along the contralateral pathway to the LSO (Figure 1). Reprinted with permission from Joris, P. X. and Yin, T. C. T. 1995. Envelope coding in the lateral superior olive. I. Sensitivity to interaural time differences. J. Neurophysiol. 73, 1043–1062.

with specializations in the calyx result in large, rapid EPSPs that excite MNTB neurons with nearly invariant synaptic delays (Trussell, L. O., 2002). Collectively, these synaptic specializations allow the physiological response properties of MNTB to be virtually identical to their GBC inputs not only in their representation of the stimulus spectrum but also in their representation of the time structure of the stimulus (Guinan, J. J. *et al.*, 1972a; Tsuchitani, C., 1997; Smith, P. H. *et al.*, 1998; Kopp-Scheinpflug, C. *et al.*, 2003; Tollin, D. J. and Yin, T. C. T., 2005). Finally, further reducing the functional delays in the contralateral pathway, MNTB inputs synapse right on or near the soma of LSO neurons while the excitatory inputs from the ipsilateral CN synapse on the distal dendrites (Cant, N. B., 1984; Helfert, R. H. *et al.*, 1992; Smith, P. H. *et al.*, 1998).

The functional implication of rapid transmission to the LSO of the contralateral inhibition is that for transient sounds or sounds with ongoing rapid AM (e.g., Figure 4) or FM, the inhibition of the discharge rate of the LSO should be nearly maximal when these stimuli are presented to the two ears with no delay between their onsets (i.e., a source at the midline). Physiological experiments have indeed shown that inhibition of LSO responses can often be maximal when the delay between the onsets of transients (Figure 5), low-frequency tones, or

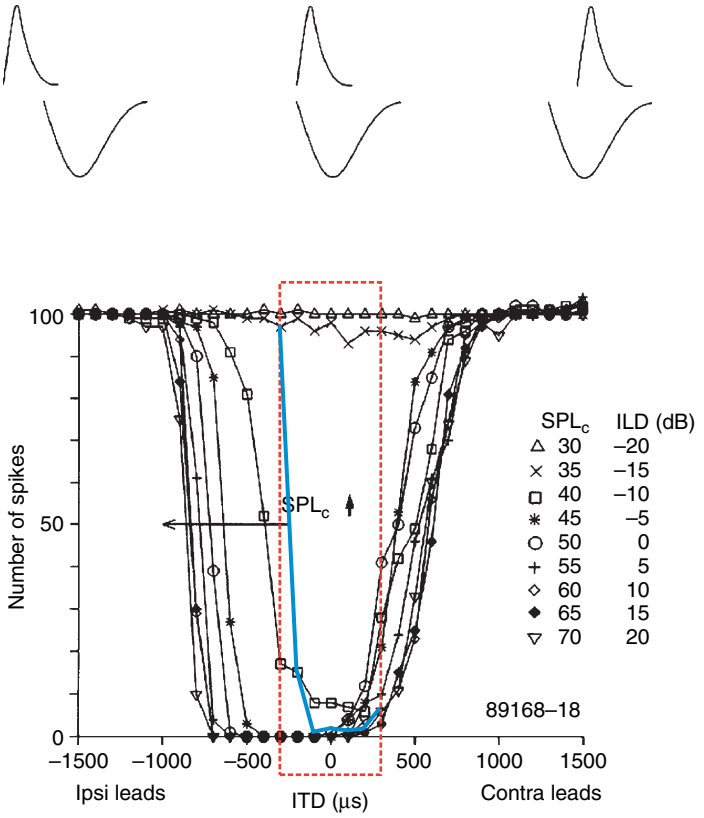

Figure 5 Lateral superior olive (LSO) neurons compare excitation and inhibition over short time intervals. Tracings at the top illustrate the relative durations of EPSPs (top, positive-going traces) and IPSPs (bottom, negative-going traces) in LSO neurons and their potential interactions as a function of the time delay between them (abscissa, bottom graph). The graph shows the number of spikes elicited from an LSO neuron as a function of both interaural time difference (ITD) (abscissa) and interaural level difference (ILD) (different symbols) in clicks presented to the two ears. For most ILDs, the response as a function of ITD has a characteristic U shape with substantial inhibition occurring primarily for ITDs between ~±500 μs. Therefore, the functional binaural integration time over which there is effective inhibition is ~1 ms. The physiological range of ITDs in cats (~±300 μs) is indicated by the box (red). The blue function plots the change in response that would likely result from the joint changes in ILD and ITD that would be expected by varying an actual sound source in azimuth. A functional consequence of the short integration time is that the ILD in transient stimuli like the clicks used in this example can still be represented by LSO neurons without the confounding effects on responses that time delays produce. Reprinted with permission from Joris, P. X. and Yin, T. C. T. 1995. Envelope coding in the lateral superior olive. I. Sensitivity to interaural time differences. J. Neurophysiol. 73, 1043–1062.

amplitude-modulated stimuli of equal level are presented to the two ears simultaneously (Caird, D. and Klinke, R., 1983; Finlayson, P. G. and Caspary, D. M., 1991; Joris, P. X. and Yin, T. C. T., 1995; Park, T. J. *et al.*, 1996; Batra, R. *et al.*, 1997; Irvine, D. R. *et al.*, 2001). Joris P. X. and Yin T. C. T. (1998) showed using two independent methods that, on average, the contralateral inhibitory input reaches the LSO within ~200 μs of the ipsilateral excitatory input. These data confirm earlier reports that the initial onset discharges to simultaneous and equal amplitude sounds could be inhibited in some LSO neurons (Boudreau, J. C. and Tsuchitani, C., 1968) and are also consistent with *in vitro* intracellular recordings of synaptic potentials that demonstrate that the relative time of arrival of evoked EPSPs and IPSPs can have a dramatic effect on the discharge probability of LSO neurons (Wu, S. H. and Kelly, J. B., 1991). The unique and remarkable anatomical and biophysical specializations observed in the long contralateral pathway to the LSO likely serve to minimize both the relative timing delays and the jitter in the synaptic delays incurred along the ILD pathway so that ILDs in the stimulus, particularly for brief, transient stimuli, can be accurately represented.

3.36.3.5 Lateral Superior Olive Neurons Have Short Integration Times

The highly accurate encoding of rapid temporal variations in stimuli by LSO afferents and the comparison of those inputs in temporal register by LSO neurons would not be necessary unless those inputs were also compared over short time intervals. For this to happen, the integration time of the comparison should be short so that a correlate of ILD is only computed over brief, temporally corresponding portions of the stimuli at each ear. Indeed, it has been shown that contralateral stimulus-evoked IPSPs recorded intracellularly in LSO neurons tend to have relatively long durations (3.2–8.1 ms) that are nearly twice the duration of ipsilaterally evoked EPSPs (1.5–4.2 ms) (Sanes, D. H., 1990). Functionally, however, the contralateral inhibition is effective in suppressing ipsilaterally evoked discharges of LSO neurons for only about ~1.0–2.0 ms (Sanes, D. H., 1990; Wu, S. H. and Kelly, J. B., 1992; Joris, P. X. and Yin, T. C. T., 1995; Park, T. J. *et al.*, 1996; Irvine, D. R. *et al.*, 2001).

To illustrate the functional integration time, Figure 5 shows an example of the responses of an LSO neuron to presentations of click stimuli to the two ears that contain combinations of ITDs and ILDs (Joris, P. X. and Yin, T. C. T., 1995). The drawings above the graph illustrate the relative durations of and the delays between the click-evoked EPSPs and IPSPs, respectively, as the ITD is varied. For a given ILD, as the ITD varied, responses were suppressed for delays ranging from ~±500 μs; in other words, IPSPs and EPSPs interacted functionally for ~1 ms. Integration times of 1–2 ms would presumably allow ongoing ILD computation for stimulus fluctuations up to ~1 kHz before synaptic inputs would be temporally integrated. Supporting this, some LSO neurons track ILDs in binaural AM stimuli at rates up to 800 Hz (Joris, P. X., 1996).

A potentially important consequence of the short integration time is that the output of the LSO neuron is still modulated monotonically as a function of ILD (Figure 5(b), blue line) despite the changes in ITD over the physiological range of ITDs in cats (±300 μs, red box; Roth, G. L. *et al.*, 1980). The neuron's response that would likely result under the natural situation where both ILD and ITD vary with source azimuth (blue line) changes in an orderly way as the source is moved from the ipsilateral (negative delays and ILDs) to the contralateral (positive delays and ILDs) side. Short integration times, then, presumably allow LSO neurons to accurately encode the ILDs of transient sounds via discharge rate without the confounding influence of time delays induced by the ITD.

3.36.3.6 Lateral Superior Olive Neurons Encode the Interaural Level Difference Present in the Sounds at the Two Ears

3.36.3.6.1 Sensitivity to interaural level differences in pure-tone stimuli

The responses of single LSO neurons are correlated with ILDs (Boudreau, J. C. and Tsuchitani, C., 1968; Guinan, J. J., Jr. *et al.*, 1972a; Caird, D. and Klinke, R., 1983; Sanes, D. H. and Rubel, E. W., 1988; Joris, P. X. and Yin, T. C. T., 1995; Park, T. J. *et al.*, 1997; Irvine, D. R. *et al.*, 2001; Tollin, D. J. and Yin, T. C. T., 2002a; Park, T. J. *et al.*, 2004).

For example, Figure 6 shows the responses of an LSO neuron to changes in the ILD of CF tones. ILD was manipulated by presenting a constant-level tone to the ipsilateral excitatory ear while varying the sound level of a simultaneously presented tone to the contralateral ear. Figures 6(a)–6(d) shows the responses at four different ILDs displayed as dot rasters and associated poststimulus time histograms

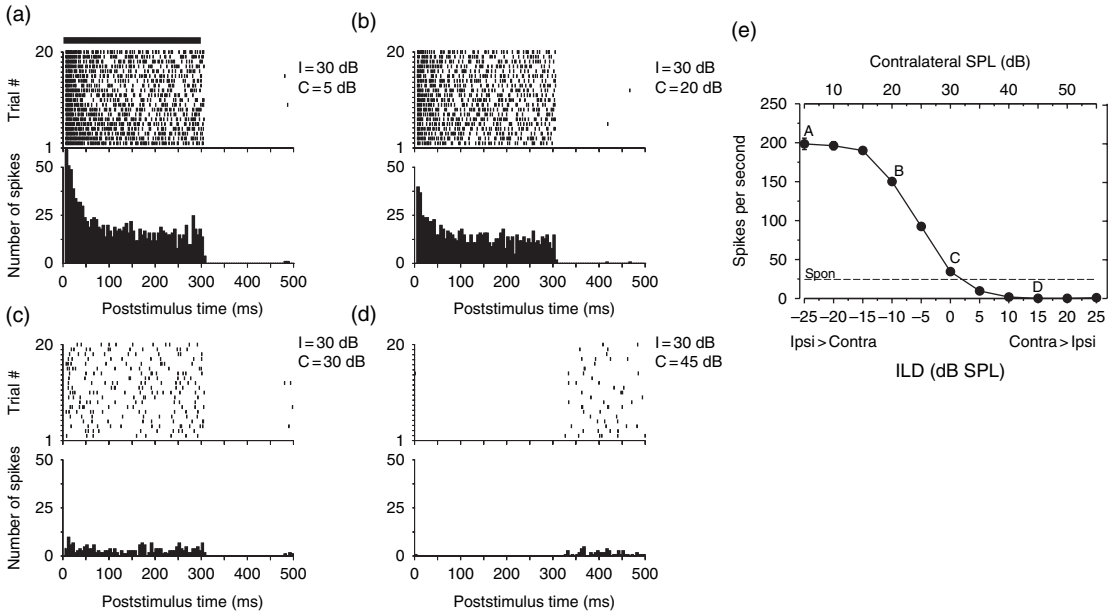

Figure 6 Lateral superior olive (LSO) neurons are sensitive to interaural level differences (ILDs) in pure tone stimuli. (a)–(d) Responses of one LSO neuron (CF (characteristic frequency) = 16 kHz) displayed as dot rasters and PSTHs to CF-tone bursts presented 20 times for each ILD (top right-hand corner). Stimulus duration was 300 ms (bar at top of (a)). The level of the tone at the ipsilateral ear was fixed at 30 dB SPL (~20 dB re: threshold) while the level of the same CF tone presented to the contralateral ear was increased. (e) Mean discharge rate ±1 SEM of the neuron computed over the duration of the stimuli and across the 20 repetitions as the level of the stimulus to the contralateral ear was increased (top abscissa), which changes the ILD (bottom abscissa). ILD is defined as the difference between the sound level at the contralateral ear and that at the ipsilateral ear so negative ILDs indicate greater sound levels at the excitatory ear. The dashed horizontal line indicates spontaneous firing rate. Reprinted with permission from Tollin, D. J. and Yin, T. C. T. 2002. The coding of spatial location by single units in the lateral superior olive of the cat. I. Spatial receptive fields in azimuth. J. Neurosci. 22, 1454–1467.

(PSTHs). The data points marked A–D in Figure 6(e) show the mean discharge rates evoked at these four ILD values. With the ipsilateral level held constant, the firing rate decreased systematically as the level of the contralateral tone was increased. For positive ILDs that favor the contralateral ear, the response was completely inhibited, with the discharge rate falling even below the spontaneous rate (horizontal dashed line), as shown for an ILD of 15 dB (Figure 6(d)). This neuron preferentially responded to stimuli with ILDs favoring the ipsilateral excitatory ear. In fact, studies have shown that most neurons in the LSO respond preferentially to ipsilateral ILDs (Boudreau, J. C. and Tsuchitani, C., 1968; Caird, D. and Klinke, R., 1983; Sanes, D. H. and Rubel, E. W., 1988; Joris, P. X. and Yin, T. C. T., 1995; Park, T. J. *et al.*, 1997; Tollin, D. J. and Yin, T. C. T., 2002a; Park, T. J. *et al.*, 2004). Extrapolating from the ILD cues actually available to cats (e.g., Figure 2), the neurons comprising each LSO, then, would likely encode information primarily about ipsilateral sound sources as most neurons would be inhibited for contralateral sources. That is, the left and right LSOs encode sources in the left and right hemispheres, respectively.

Neurons in the LSO can collectively, across the population, respond to ILDs over a range sufficient to encode the range of physical ILDs that are expected from acoustical measurements (see Figure 2(b)). Moreover, individual neurons are sensitive to different absolute ranges of ILDs and can also signal the ILD for different types of acoustical signals provided the stimuli fall within the frequency selectivity of the neuron (Boudreau, J. C. and Tsuchitani, C., 1968; Caird, D. and Klinke, R., 1983; Sanes, D. H. and Rubel, E. W., 1988; Joris, P. X. and Yin, T. C. T., 1995; Batra, R. *et al.*, 1997; Park, T. J. *et al.*, 1997; Tollin, D. J. and Yin, T. C. T., 2002a; Park, T. J. *et al.*, 2004). However, there are complications to the notion that LSO neurons faithfully represent ILDs. First, responses generally are not invariant to changes in the more global aspects of the stimuli. For example, the responses of most LSO neurons change dramatically as the overall level of the stimuli is changed despite a constant ILD (Tsuchitani, C. and

Boudreau, J. C., 1969; Tollin, D. J. and Yin, T. C. T., 2002a; Park, T. J. *et al.*, 2004). Second, as reviewed in earlier sections, for some stimuli large delays in the contralateral input to the LSO can change the discharge rate irrespective of any ILD changes (e.g., Figure 4). Consequently, a given physical ILD in a stimulus does not always correspond to a fixed discharge rate. It is likely that populations of LSO neurons and/or the differential responses of comparable LSO neurons comprising the left and the right LSOs compute a more accurate correlate of the ILD (e.g., Park, T. J. *et al.*, 2004).

3.36.3.6.2 Sensitivity to interaural level differences in virtual space (VS) stimuli that mimic free-field sounds

Most physiological studies of ILD coding have used stimuli presented over headphones to the two ears. But what about the ability of LSO to encode ILDs present in more natural stimuli, in which the ILDs (and ITDs and spectral shape cues) are created by the interactions of the sound waveforms with the head and pinnae (e.g., Figure 2)? Can LSO neurons encode the ILDs present in broadband stimuli that contain all the acoustical cues to location in their native combinations, such as would be the case for sounds presented in the free field? Complicating any discussion of ILD coding of free-field sources is the fact that LSO neurons are sensitive not only to ILD, but also to each of the other cues to azimuth when they are presented in isolation; that is, certain types of ITDs (Caird, D. and Klinke, R., 1983; Finlayson, P. G. and Caspary, D. M., 1991; Joris, P. X. and Yin, T. C. T., 1995; Park, T. J. *et al.*, 1996; Batra, R. *et al.*, 1997; Irvine, D. R. *et al.*, 2001; Tollin, D. J. and Yin, T. C. T., 2005) and overall sound level, which is important for the spectral cues (Tsuchitani, C. and Boudreau, J. C., 1966; Tsuchitani, C., 1997; Tollin, D. J. and Yin, T. C. T., 2002a). Moreover, free-field studies of spatial sensitivity are further complicated by the fact that the cues covary with changes in source azimuth. So without acoustical measurements, it is difficult to determine which cues or combinations of cues were responsible for the neural responses.

This issue of which cues contribute to the spatial selectivity of LSO neurons was recently addressed in experiments where broadband noises were first filtered by left- and right-ear HRTFs from a desired location and then presented over earphones (Tollin, D. J. and Yin, T. C. T., 2002a; 2002b). HRTFs contain the complete spatial- and frequency-dependent transformation a sound undergoes as it travels from source to eardrum (see Figure 2(a)), so HRTF-filtered sounds presented to the two ears from the earphones are comparable to those that would have arisen had the cat been stimulated by the sound stimuli delivered from that chosen location in space. This is the basis of the so-called VS technique. The obvious advantage of the VS technique is that the stimuli contain all the cues to location and the cues can be computed by the experimenter, which facilitates the correlation of a neuron's response with the values of the cues.

Figure 7 shows the responses of the same LSO neuron as in Figure 6 but to broadband noise from five different VS azimuths along the horizontal plane under two different stimulus conditions. When the stimuli were presented to both ears so that all the acoustical cues to location were presented in their natural combinations (Figure 7(a), normal condition), there were vigorous responses for ipsilateral sources, diminishing responses at the midline, and inhibited responses for sources in the contralateral field. This pattern of responses is partly expected because this neuron was sensitive to ILDs (e.g., Figure 6) and for ipsilateral sources, the sound level to the excitatory ear, as processed through the frequency selectivity of the neuron, exceeded the sound level at the inhibitory ear and *vice versa* for sources in the contralateral field. The experiment was repeated with stimuli presented only to the ipsilateral ear, the contralateral earphone having been turned off (Figure 7(b), ipsi-only condition). The contribution of contralateral inhibition to spatial sensitivity was clear, as evidenced by the increased responsiveness for sounds at all locations, particularly at the midline and for contralateral locations where the inhibition seen in the binaural condition (Figure 7(a)) was no longer apparent. The binaural sensitivity of this neuron is further illustrated by plotting the responses as continuous dot rasters for 21 different azimuths in the frontal hemisphere for the normal binaural (Figure 7(a), right) and monaural ipsi-ear only (Figure 7(b), right) conditions. By comparing the rasters as a function of azimuth for the two conditions, the effect of the contralateral inhibition is evident. Figure 9(a) plots the mean discharge rate as a function of azimuth for this neuron, which we call the spatial receptive fields (SRFs) in azimuth.

Different LSO neurons were shown to be sensitive to variations in the azimuth of sounds consistent with their ipsi-excitatory and contra-inhibitory binaural interaction as assessed from the pure tone stimuli (Tollin, D. J. and Yin, T. C. T., 2002a; 2002b).

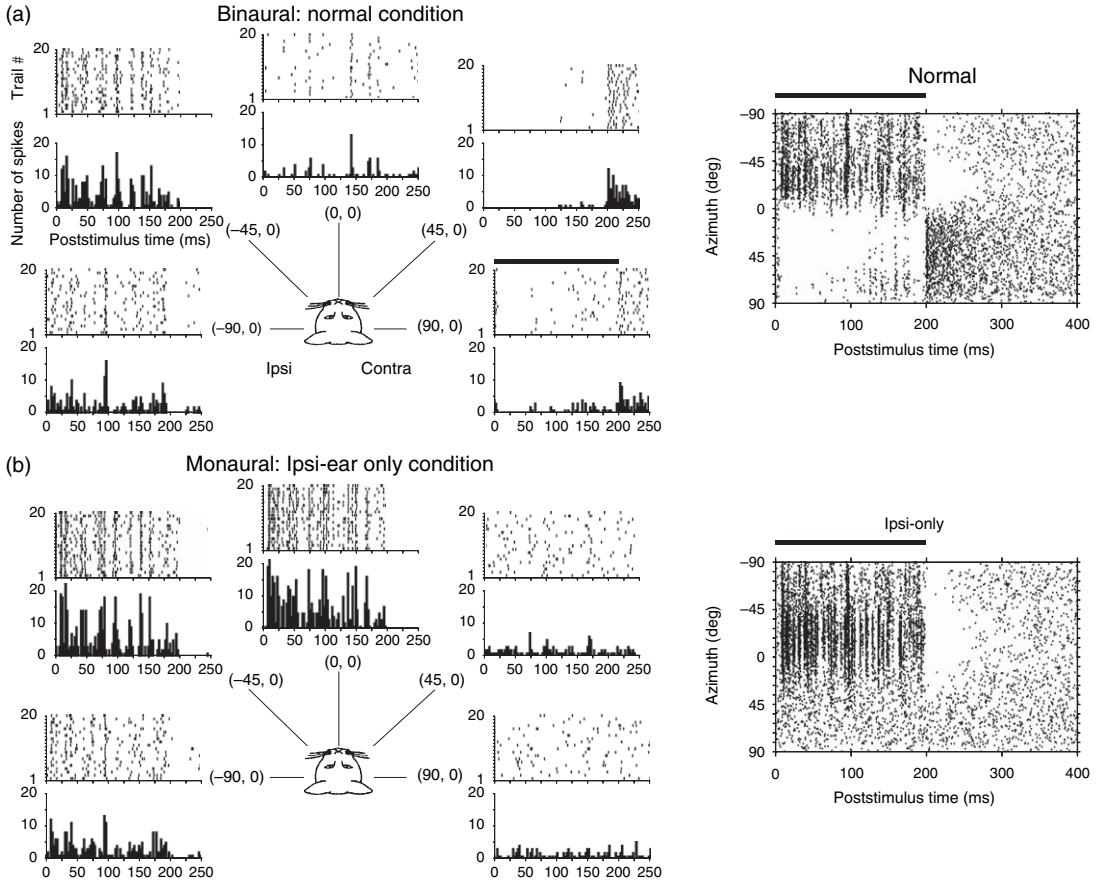

Figure 7 Lateral superior olive (LSO) neurons are sensitive to the azimuthal location of virtual-space stimuli. Responses of the same LSO neuron in Figure 6 shown as dot rasters and associated PSTHs to variations in the virtual-space azimuth of 200-ms broadband noise (black bar) stimuli. Source azimuth was manipulated by filtering noise with a left- and right-ear head-related transfer function (HRTF) appropriate for each position and presenting the stimuli over earphones. The stimuli were presented 20 times each at 21 different azimuths (right column), the responses to five of which are shown in detail (left column), and under two conditions, binaural (a) and monaural (b). (a) Responses for the normal binaural condition for which all the acoustical cues to location were presented to the two ears in their natural combination at each azimuth. The strong responses for ipsilateral azimuths and the apparent inhibition for contralateral azimuths were expected because ipsilateral sources result in higher sound levels at the excitatory ear relative to those at the contralateral ear, whereas contralateral sources result in higher sound levels at the inhibitory ear than at the excitatory ear. The raster to the right plots the responses of the neuron for all 21 azimuths. Note the strong suppression of responses during stimulus presentation for contralateral (positive) azimuths. (b) Responses in the monaural ipsi-ear only condition. The stimulus was presented only to the excitatory ear as a function of azimuth; the contralateral earphone was simply shut off. At all azimuths, responses are greater than was the case for binaural stimulation revealing the effect of the contralateral inhibition observed in the example shown in (a). The raster to the right shows the responses for all 21 azimuths. Inhibition that was apparent in the binaural condition (a) is no longer present. Reprinted with permission from Tollin, D. J. and Yin, T. C. T. 2002. The coding of spatial location by single units in the lateral superior olive of the cat. I. Spatial receptive fields in azimuth. J. Neurosci. 22, 1454–1467.

Consistent with that found with tone stimuli, all neurons appeared to encode information about sound location only for stimuli in the ipsilateral field as most were inhibited for sources contralateral to the midline (Figure 8; normalized SRFs).

Strong correlations were documented between the shapes of the SRFs as a function of the CF of the neuron being studied and the azimuth-dependent patterns of ILD actually present in a narrow band of frequencies around the CF of the neurons (see Figure 2(b)). For example, neurons with CFs <10 kHz had sigmoidally shaped SRFs with shallow rate-azimuth slopes at the midline (Figure 8, black) while neurons with CFs >10 kHz (Figure 8, red) had more complex-shaped SRFs and steeper rate–azimuth slopes at the midline. The sensitivity to

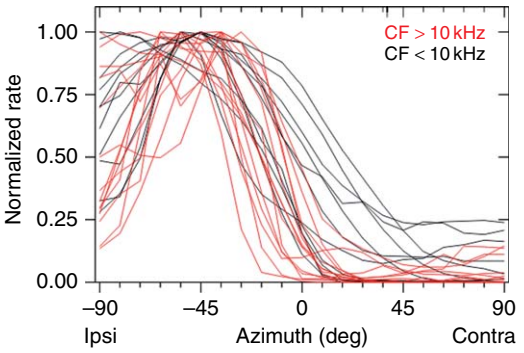

Figure 8 Spatial receptive fields (SRFs) in azimuth of lateral superior olive (LSO) neurons. LSO neurons encode azimuth for sources in the ipsilateral hemisphere as the responses of most neurons for contralateral sources are suppressed. SRF shape also depends upon the characteristic frequency (CF) of each neuron. Neurons with CFs <10 kHz (black) have sigmodally shaped SRFs and the slope of the rate-azimuth function near the midline is shallow. Neurons with CFs >10 kHz (red) have complex SRFs that exhibit peaks and dips and the slope of the rate–azimuth function near the midline is steep. In many ways, the CF dependence on SRF shape mirrors the CF dependence that the interaural level difference (ILD) cue itself displays as a function of azimuth (e.g., Figure 2(f)). This reinforces the hypothesis that LSO neurons are encoding the ILD computed through their frequency selectivity. Reprinted with permission from Tollin, D. J. and Yin, T. C. T. 2002. The coding of spatial location by single units in the lateral superior olive of the cat. I. Spatial receptive fields in azimuth. J. Neurosci. 22, 1454–1467.

azimuth in LSO neurons was also found to be maintained over a wider range of overall sound levels under binaural than monaural ipsi-only stimulation where the neural responses saturated at higher levels (Tollin, D. J. and Yin, T. C. T., 2002a).

But what about the documented sensitivity of LSO neurons to the other cues and what do those cues contribute, if any, to the SRFs? To test this, the VS stimuli were digitally manipulated in such a way as to hold constant (or vary) with changes in stimulus azimuth each of the localization cues in turn while varying (or holding constant) the remaining cues (Tollin, D. J. and Yin, T. C. T., 2002b). Figure 9 shows the normal binaural and ipsi-only SRFs (Figure 9(a)) for the same neuron as in Figures 6 and 7 and the SRFs that result from manipulating the ILD cues (Figure 9(b)), the ITD cues (Figure 9(c)), and the monaural spectral cues (Figure 9(d)). In each of these three panels, the normal SRF is shown for reference (filled circles) and the two additional plots show the effect on the SRF of manipulating one of the cues by holding it at a constant value for all azimuths while letting the remaining cues vary naturally (open squares) or allowing only that cue to vary with azimuth while holding the remaining two cues constant (red squares). When a cue or cues were held constant, they were set to values consistent with the cues provided by a stimulus delivered from the midline (i.e., 0 dB ILD, 0 μs ITD, and the spectral shape for this position). When the ILD cue was manipulated it was done so by appropriately increasing or decreasing the amplitude of the stimuli presented to each ear until the desired ILD, as computed through a 1/3-octave Gaussian filter centered on the CF of the unit being studied, was obtained.

Through the selective manipulation of the cues, it was determined directly that the ILDs present in a small band of frequencies around the CF of each neuron were the primary determinants of the VS fields that were measured under the normal binaural conditions for which all the cues varied naturally (Tollin, D. J. and Yin, T. C. T., 2002b). For example, when the ILD cue varied naturally with azimuth but the ITD and the monaural spectral shape cues held constant (Figure 9(b), Δ-ILD), the SRF was similar to that measured when all three of these cues varied naturally with azimuth. The ITD and spectral cues were held fixed for all azimuths in the Δ-ILD condition, so the close correspondence between the resulting SRF and the normal SRF strongly implicate the ILD in the narrowband of frequencies around the CF of the stimuli as the primary determinant of the normal SRF for this neuron. Supporting this notion, for those manipulation conditions where the ILD cue in the same narrowband was held constant at 0 dB for all azimuths (red squares in Figure 9(c), Δ-ITD condition and in Figure 9(d), Δ-ISD condition), there was no modulation of the response with azimuth. Although ILD was held constant at 0 dB in those latter two conditions, the ITD and spectral cues were changed naturally, but the response was not modulated. Hence, ILDs and not ITDs or the monaural spectral shape determined the SRF for this LSO neuron. Similar results were obtained across a population of LSO neurons with different CFs (Tollin, D. J. and Yin, T. C. T., 2002b). The finding that ITDs and the spectral cues contributed little to the spatial selectivity is consistent with earlier reports of ILD dominance in LSO responses to complex sounds with limited combinations of physiologically plausible ITDs and ILDs (Caird, D. and Klinke, R., 1983; Joris, P. X. and Yin, T. C. T., 1995). However, for stimuli of transient nature, ITDs

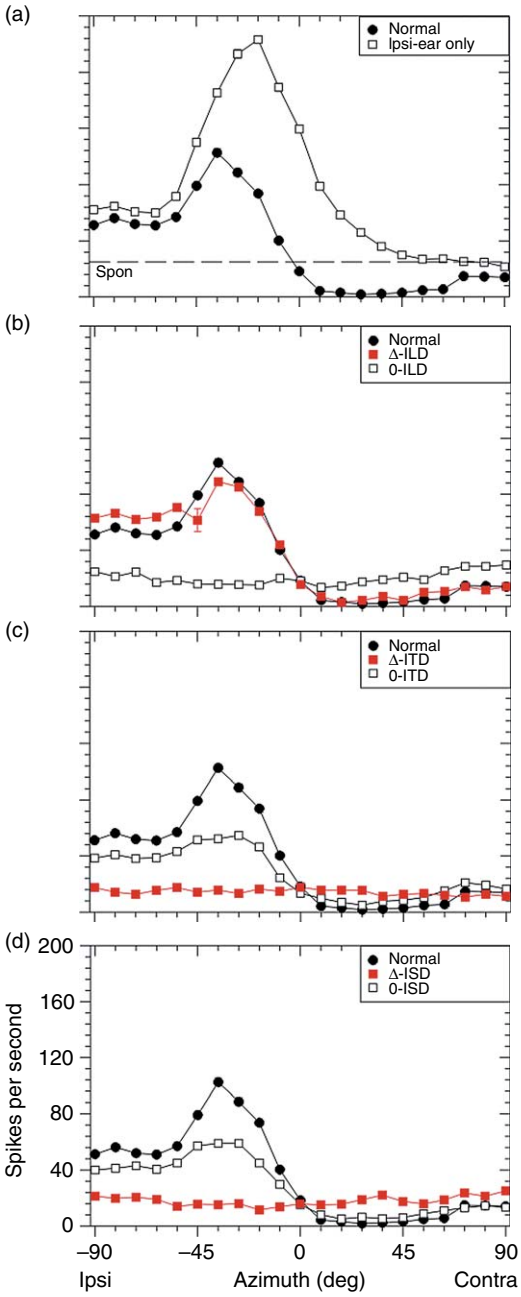

Figure 9 The primary determinant of the spatial selectivity of lateral superior olive (LSO) neurons is the interaural level difference (ILD) cue. (a) The spatial receptive field (SRF) in azimuth of the same LSO neuron shown in Figures 6 and 7 plotted as the mean discharge rate ± 1 SEM for both the normal binaural condition (filled circles) and the monaural ipsi-ear only condition (open squares). The inhibition resulting from contralateral sound sources (e.g., Figure 7(a)) is visible in the SRFs. The contribution of the contralateral inhibition to the SRF can be seen by comparing the normal SRF to the ipsi-ear only SRF. The dashed line indicates the spontaneous discharge rate. (b)–(d) Effects on the SRF in azimuth of manipulating the three cues to location. Each cue was either held constant while the remaining two cues were allowed to vary naturally with changes in the azimuth of the sound sources (open squares) or changed naturally with azimuth while the remaining cues were held at fixed values (red squares). Cues held constant took values consistent with those for the midline location; that is, zero ITD and ILD and monaural spectral shape cues identical for a stimulus at the midline. For comparison, the normal binaural SRF is shown in each panel (filled circles). (b) Effects of manipulating the ILD cues. (c) Effects of manipulating the ITD cues. (d) Effects of manipulating the monaural spectral cues. Only for those conditions were the ILD cues were changed with azimuth (Δ-ILD in (b), 0-ITD in (c), and 0-ISD in (d)) were the responses similar to the response under the normal binaural condition where all the cues varied with azimuth. As shown in (c) and (d), there was little response modulation as either ITD (Δ-ITD) or the spectral cues (Δ-ISD) were varied in isolation with azimuth.

can have a larger effect through the mechanisms described in Figure 4; however, the ranges of ITDs used in those experiments were often well outside the physiological range (Caird, D. and Klinke, R., 1983; Park, T. J. *et al.*, 1996; Irvine, D. R. *et al.*, 2001).

3.36.4 Comparative Studies Implicate the LSO as Necessary for ILD Processing

There are marked differences in the relative sizes of the major nuclei comprising the SOC across mammalian species (Harrison, J. M. and Irving, R., 1966; Irving, R. and Harrison, J. M., 1967; Glendenning, K. K. and Masterton, R. B., 1998; Moore, J. K., 2000). The correlation between the sizes of the SOC nuclei and the availability and use of the localization cues provides important clues to the different functions of these nuclei. On the one hand, mice, hedgehogs, and echolocating bats have extremely large and well-developed LSO and MNTB but small and sparse MSO. On the other hand, in primates, including humans, the LSO and MNTB tend to be small but the MSO large and well developed. In the middle are mammals, like cats, dogs, chinchillas, and guinea-pigs, for which all three nuclei are well developed. Despite differences in overall size, there is a consistent parallel development of MNTB and LSO in virtually all species examined such that mammals with large LSOs typically also have large MNTBs and *vice versa*. This finding supports the hypothesis that the LSO and the ipsilateral MNTB form a functional circuit. Interestingly, in a study of 53 mammalian species, while all mammals possessed a LSO and MNTB, the MSO was the only nucleus out of 10 examined that was found to be entirely absent in some mammals (Glendenning, K. K. and Masterton, R. B., 1998).

If both the LSO and the MSO contribute to sound localization, why are there large variations in the relative sizes of the MSO and LSO in different species? One possibility is that the types and magnitudes of the localization cues available to these species differ because of variations in the diameter of the head (see Section 3.36.2). For example, ITDs are not useful for animals with very small heads because the magnitude of the maximum ITDs is small. Yet in these same mammals large ILDs are available, but only for high-frequency sounds with wavelengths smaller than the diameter of the head. Based on this logic, it has been hypothesized that the main selective pressure for the evolution of high-frequency hearing in mammals has been the need to use ILDs for accurate localization, rather than for communication (Masterton, B. *et al.*, 1969). Supporting this hypothesis, there is a large significant correlation between high-frequency hearing and interaural diameter so that mammals with smaller heads have higher-frequency hearing limits than those with larger heads (Masterton, B. and Diamond, I. T., 1967). Moreover, anatomically, the ratios of the sizes of the major nuclei of the SOC are also closely related to the frequency range of hearing in the species (Masterton, B. and Diamond, I. T., 1973) so that, in general, the higher the frequency the animals can detect, the larger and more developed the MNTB/LSO circuit, whereas the lower the frequencies that animals can detect, the larger and more well-developed the MSO.

Given the comparative anatomical findings and the useable localization cues available to different species, Masterton B. and Diamond I. T. (1967) suggested that the MSO encodes ITDs and the LSO encodes ILDs. Psychophysical data supports this hypothesis. For example, the hedgehog lacks an MSO and cannot use ITDs to localize low-frequency sounds, but can use ILDs for high frequencies (Masterton, B. *et al.*, 1975). Horses and cattle have diffuse and disorganized LSOs and cannot use ILDs to localize high-frequency sounds (Heffner, R. S. and Heffner, H. E., 1986). In general, those species that localize low-frequency sounds poorly or that rely exclusively on high-frequency sound have well-developed LSO and MNTB and poorly developed MSO (Irving, R. and Harrison, J. M., 1967; Masterton, B. *et al.*, 1969; Masterton, B. and Diamond, I. T., 1973; Masterton, B. *et al.*, 1975; Heffner, R. S. and Heffner, H. E., 1986). Conversely, animals that localize high-frequency sounds poorly or that typically use low-frequency sounds for communication, like humans, tend to have a prominent MSO but a smaller LSO and MNTB (Harrison, J. M. and Feldmam, 1970; Moore, J. K., 2000). Finally, in species that are sensitive to low and high frequencies, like the cat, both the MSO and the LSO/MNTB are prominent and they are able to locate accurately sounds of both low and high frequencies.

Naturally, there are exceptions. For example, many hoofed mammals including pigs, cattle, horses, and goats possess a LSO and MNTB, but seem unable to use ILDs in high-frequency sounds for localization (Heffner, R. S. and Heffner, H. E., 1986; 1989). And due to increased head diameter and good low-frequency hearing humans have a predictably smaller

LSO; however, the MNTB is either very small (Richter, E. A. *et al.*, 1983) or nonexistent (Moore, J. K., 2000; Bazwinsky, I. *et al.*, 2003) despite our extraordinary behavioral sensitivity to ILDs over virtually the entire range of hearing (Mills, A. W., 1960). Given these important exceptions, in addition to head diameter and the differential availability of the ITD and ILD cues, there must have been additional evolutionary pressures for the divergent development of the SOC nuclei across mammals. Interestingly, head diameter alone accounts for only a fraction of the variance of sound localization abilities in a large number of mammals tested (Heffner, R. S., 1997). The one factor (among many tested) that can account for much of this variability is the width of the best field of vision (Heffner, R. S., 1997), supporting earlier hypotheses that the primary function of the binaural auditory system is to direct the eyes to the source of the sound to permit further visual inspection (Harrison, J. M. and Irving, R., 1966). Taken as a whole, these comparative studies strongly implicate the LSO as necessary for ILD processing consistent with our review of the anatomical and physiological data above.

3.36.5 Conclusion

The duplex theory posits that the localization of low- and high-frequency sounds is based on ITDs and ILDs, respectively. Early in the ascending auditory pathway, anatomical and physiological specializations in the nuclei of the SOC form a neural basis for the duplex theory where the MSO is thought to encode ITD cues while the LSO, along with the inhibitory input from the MNTB, is thought to encode ILDs. Acoustically, ILDs are available predominately for high frequencies with wavelengths smaller than the diameter of the head and depend jointly on sound source azimuth and frequency. The processing of ILD was shown to be dependent upon several remarkable specializations in the anatomy, biophysical characteristics, and the physiological response properties of the LSO neurons and their afferents. The specializations in the LSO afferents permit the faithful representation of the spectral and temporal attributes of the sound arriving at the two ears. And the specializations at the LSO allow ILD to be encoded based on these representations on nearly a frequency-by-frequency and time-by-time basis. From a functional perspective, comparative studies of the SOC nuclei, the available localization cues, and the localization abilities of a large number of mammals have substantiated these findings. In summary, the literature reviewed here collectively supports the hypothesis that the LSO is the initial ILD processor in the mammalian ascending auditory pathway.

Glossary

binaural sound localization Directional hearing that requires two ears. These processes are important for localization based on the interaural time and level differences that are associated with sources in the horizontal plane. See interaural time difference, interaural level difference.

directional transfer function Acoustic measure of the outer ear's responses to free-field sounds. Unlike the head-related transfer function, this measure is based on filtering effects at a single source location versus common effects at all locations. The directional transfer function reveals which acoustic properties are idiosyncratic for the location and therefore of greatest directional significance. See head-related transfer function.

dorsal acoustic stria The output pathway of the dorsal cochlear nucleus. The projections convey spectral representations that are created in the brainstem to the inferior colliculus (ICC). See dorsal cochlear nucleus.

dorsal cochlear nucleus The dorsal subdivision of the cochlear nucleus receives inputs from the auditory nerve and projects to the inferior colliculus by way of the dorsal acoustic stria. The structure is implicated in the initial processing of spectral cues for sound localization. See spectral cues for sound localization.

head-related transfer function (HRTF) Acoustic measure of the outer ear. The transfer function is obtained by placing a probe microphone in the ear canal and measuring responses to free-field auditory stimuli. Unlike the directional transfer function, this is an absolute measure of the acoustic properties of the ear. See directional transfer function.

head shadow Attenuation created when the ear obstructs the path of a free-field sound en route to the ear. These effects are determined by the wavelength of the sound and the physical dimensions of the head. The attenuation is largest for sounds with short wavelengths and establishes the interaural level differences that dictate high-

frequency localization in the horizontal plane. See interaural level differences, lateral superior olive.

horizontal plane Imaginary plane that intersects the head at the interaural axis. A rotation in the plane proceeds front, right, back, left, and front. Tests in this plane emphasize the importance of binaural localization cues. See binaural sound localization.

inferior colliculus The auditory midbrain integrates inputs from all of the major auditory nuclei and a number of nonauditory sources. Ascending pathways with important localization roles include the essentially monaural dorsal cochlear nucleus, and the binaural lateral and medial superior olives. See dorsal cochlear nucleus, lateral superior olive, medial superior olive.

interaural level difference Difference in the level of a free-field stimulus at the two ears. The stimulus is attenuated at the ear remote to the source by the sound shadowing effect of the head. See head shadow.

interaural time difference Difference in the time of arrival of a free-field auditory stimulus at the two ears. The stimulus is delayed at the ear remote to the source by the increased distance the sound wave must travel. See medial superior olive.

lateral superior olive Binaural nucleus that receives a direct excitatory input from the ipsilateral ventral cochlear nucleus and an indirect inhibitory input from the contralateral ventral cochlear nucleus via the trapezoid body. The excitatory–inhibitory interaction endows lateral superior olive neurons with a sensitivity to interaural level differences. These binaural cues dictate high-frequency localization in the horizontal plane. See interaural level difference, horizontal plane.

lesion Surgical destruction of a neuroanatomical pathway. Resulting behavioral deficits confirm the functional significance of the damaged structure.

medial superior olive Auditory brainstem nucleus that receives bilateral excitatory inputs from the ventral cochlear nuclei. The binaural excitatory interactions are the primary site for the processing of interaural time differences. These binaural cues dominate low-frequency sound localization in the horizontal plane. See interaural time difference, horizontal plane.

median plane Imaginary plane that intersects the head at the vertical axis. A rotation in the plane proceeds front, above, back, below, and front. Tests in this plane reveal the importance of monaural localization cues. See monaural sound localization.

monaural sound localization Directional hearing in the absence of binaural localization cues. The process is demonstrated by testing impaired listeners with monaural deafness, impeded listeners with one ear plugged or partially occluded, and normal listeners attending to the median plane where binaural cues are minimized. See binaural sound localization.

spectral cues for sound localization Directional information arising from the acoustic transfer function of the outer ear. Reflections and diffractions of sound energy shape the high-frequency spectrum of complex sounds with directionally dependent notches and peaks. These cues play a dominant role in monaural sound localization. See head-related transfer function, directional transfer function, monaural sound localization.

trapezoid body Binaural pathway linking the cochlear nuclei to the superior olives. Lesions of the pathway produce profound localization deficits in the horizontal plane because they disrupt the processing of interaural time and level differences. See interaural time differences, interaural level differences, binaural sound localization.

virtual sound field Sounds that are delivered through headphones but impart the perception of externalized spatial coordinates because they convey synthetic sound localization cues. The sounds may represent the cues in isolation, in combination, or in competition to determine the acoustic basis of directional responses.

3.37.1 Overview

Monaural sound localization is traditionally defined in three experimental contexts: impaired listeners with monaural deafness, impeded listeners with one ear plugged or partially occluded, and normal listeners attending to the median plane where binaural cues are minimized. Under these conditions, source location is derived from spectral features that are added to complex sounds by the transfer function of

the head and external ear. These acoustic cues and their initial representation in the auditory system are essentially monaural. Nevertheless, there is good evidence that spectral information takes on binaural properties at higher processing levels and exerts a pervasive influence on the localization of both elevation and azimuth. This chapter uses the term monaural to distinguish these processes from the binaural comparisons of interaural time and levels differences (ITDs and ILDs, respectively) that are described elsewhere in this publication.

We begin by summarizing the acoustic basis of monaural sound localization. Classical studies continue to provide informative descriptions of the human head-related transfer functions (HRTFs) at low-frequency. Modern techniques push these measures to higher frequencies with richer spectral detail. Differences between absolute HRTF measures and directional transfer functions (DTFs) are explained. This latter measure emphasizes acoustic information that can only be revealed by identifying the uncommon features of individual HRTFs.

Virtual space stimuli derived from HRTF acoustics provide a solid foundation for neurophysiological characterizations of the mechanisms that shape directional hearing. These representations are followed from a generalized peripheral coding of monaural localization cues to specialized pathways of the dorsal cochlear nucleus and inferior colliculus (ICC). This extensive literature is organized by the concept of a discrete spectral processing pathway that functions in parallel with binaural localization processes.

A section on acoustic manipulations of the spectral processing pathway reviews a century of research with monaural listeners, ear plugging procedures, and spectral manipulations. Subsequent psychoacoustic studies with more sophisticated signal processing techniques have elaborated on these early accounts but not contradicted their basic findings. A striking aspect of this classic work is its ability to provide timeless insights into constantly evolving physiological characterizations.

A section on lesions of the spectral processing pathway explores the neuroanatomical basis of monaural sound localization. Although the definitive behavior/ablation studies of Masterton R. B. and Neff W. D. were designed to explicate the central processes that govern horizontal localization, the universal importance of monaural spatial hearing is highlighted by the patterns of recovery that follow destruction of the binaural system.

The descriptions of monaural sound localization here rely heavily on anatomical, physiological, and behavioral data from domestic cats. Another section on species comparisons of the spectral processing pathway addresses the potential specificity of specialized localization processes by relating directional acuity to the brainstem physiology of common mammalian species. Although behavioral tests are lacking in this area of comparative hearing, interesting links exist between the keen localization sense of predatory species and physiological specializations for monaural spectral coding.

3.37.2 The Acoustic Basis of Monaural Sound Localization

When sound propagates to the eardrum, it is shaped by the directional filtering properties of the HRTF. The HRTF describes the linear distortion of the sound's amplitude and phase spectrum by the reflective, dispersive, and diffractive properties of the torso, head, and pinna (Kuhn, G. F., 1987). The resulting patterns of interference combine to increase and decrease sound energy entering the ear canal. The constructive or destructive nature of interference is determined by the wavelength of the sound and the angle of incidence upon which it impinges on the ear. Consequently, HRTF-based spectral peaks and nulls (notches) change with the direction of a sound source providing robust localization cues.

3.37.3 Early Studies of Human Head-Related Transfer Functions

Early studies of the acoustic basis of human sound localization were strongly influenced by Lord Rayleigh's duplex theory (Rayleigh, L., 1907). The theory postulates the existence of two frequency-dependent processes. Low-frequency sounds are localized on the basis of ITDs and high-frequency sounds by ILDs.

Contemporary psychoacoustic assessments of human sound localization offered behavioral proof of the dual processing mode (Hartley, R. V. L. and Fry, T. C., 1921; Stevens, S. S. and Newman, E. B., 1936). Systematic errors were noted when pure tone localization was measured in the horizontal plane. The largest deficits occurred at intermediate frequencies, revealing the transition between reliable ITD and ILD cues. To a first approximation, these localization patterns could be explained by simple

geometric models that considered the physical dimensions of the head, the wavelength of the stimulus, and the direction of the sound source (Teranishi, R and Shaw, E. A. G., 1968; Woodworth, R. S., 1938).

Early characterizations of the human HRTF offered empirical support for geometric interpretations of horizontal localization. Wiener F. M. and Ross D. A. (1946) obtained these data by inserting a small, flexible probe microphone deeply into the ear canal of human subjects. The combined directional filtering effects of the torso, head, and ear were measured by recording the transformation of sound pressure near the eardrum relative to free field. An example of these measures is shown in Figure 1, which plots the average gain of 6–12 adult men at three locations in the horizontal plane. Additional measures in women were not published but apparently did not differ significantly from men.

Several features of the transfer functions are noteworthy. First, virtually all of the gains are greater than zero. The outer ear acts as an acoustic amplifier that is most efficient at frequencies between 2 and 5 kHz, where signal levels can increase by more than 20 dB relative to free field. The boost in signal energy is created by the quarter-wave resonances of the ear canal and surrounding concha (Shaw, E. A., 1974a). This property of the outer ear enhances signal detection but is not inherently directional. A similar gain profile is observed at the three locations.

Two sources of potential directional information are visible in Figure 1. As the sound location moves from in front of the observer (0° azimuth) to the ear with the probe microphone (90° azimuth), the HRTF translates to a higher gain. The shift is produced by a lessening of the head's sound shadow; that is, the attenuation of the sound by head reflections. A microphone in the contralateral ear would show a concomitant decrease in gain for the same movement because the head would more effectively block the stimulus. The resulting ILD is an essential cue for horizontal localization.

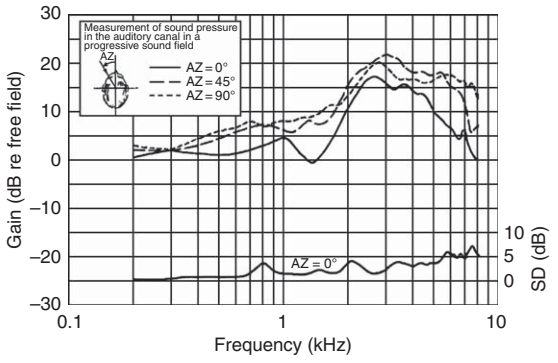

Figure 1 Gain of the head-related transfer function (HRTF) at three azimuths (AZs) in the horizontal plane. Each function represents the average of 6–12 adult men. Variation between subjects is indicated by the SD of frequency measures at 0° azimuth (bottom). Reused with permission from Wiener, F. M. and Ross, D. A. The Journal of the Acoustical Society of America, 18, 401 (1946). Copyright 1946, Acoustical Society of America.

The magnitude of the head shadow depends on the wavelength of the sound in relation to the observer's head size. The functions converge at long wavelengths below 400 Hz and diverge by as much as 15 dB at short wavelengths above 4 kHz. As a result, the ILD increases in magnitude and exerts a more direct influence on localization behavior at higher frequencies. The binaural disparity may be conveyed by broadband sounds or simple tones.

Further inspection of high-frequency filtering effects reveals that the acoustic axis of the outer ear is pointed slightly forward. Sounds reaching the ear canal from 45° are less attenuated than the more forward or eccentric locations. By analogy to retinal acuity, this preferred path has been designated the *acoustic fovea* (Middlebrooks, J. C., and Green, D. M., 1991).

A second directional cue is communicated by changes in the spectral shape of the HRTFs. Each function reflects movements of sound source azimuth with a unique maximum gain. The frequency of the prominent null seen in the 0° HRTF is similarly affected by movements in elevation that are not shown here. These spectral peaks and notches are only fully represented in broadband sounds. As a result, sound localization in the horizontal plane is sensitive to manipulations of stimulus bandwidth (Butler, R. A. and Flannery, R., 1980; Flannery, R. and Butler, R. A., 1981) and accurate localization in the median plane is virtually impossible for narrowband stimuli (Blauert, J., 1969/1970; Middlebrooks, J. C., 1992). These perceptual effects will be described later.

The stability of the HRTF measures is indicated by standard deviations (SDs) at the bottom of Figure 1. The statistical analysis was applied across subjects to each frequency in the HRTF at 0° azimuth. Although variation was quite low at low frequencies, the SD progressively increased at higher frequencies. This variability arises from the inconsistency of high-frequency acoustic measures (Wightman, F. L. and Kistler, D. J., 1989a), as well as actual individual differences (Middlebrooks, J. C., 1999a).

3.37.4 Modern Studies of Human Head-Related Transfer Functions

Early studies of the human HRTF provide only partial descriptions of the spectral features that are critical for monaural sound localization. Technical limitations of the era made it impossible to record inside the ear canal at frequencies approaching the upper bounds of human hearing. When recordings were possible, measurements were often made at discrete frequency steps and the transfer function estimated by interpolation. This lack of sampling content and resolution obscured the potential perceptual significance of directional changes in the sharp spectral features that populate high frequencies of the HRTF. Modern acoustic studies have focused on expanding the accurate characterization of these directional filtering effects.

This new approach to human sound localization may be viewed as a three stage process (for a review, see Wightman, F. L. *et al.*, 1987). The acoustic properties of the HRTF are measured at free-field locations. The properties are imposed upon synthetic stimuli to create a virtual sound field (VSF) that simulates the directional properties of the HRTF in closed field. The fidelity of the synthesis is verified by asking subjects to identify the apparent free-field location of VSF stimuli that are presented with headphones. Psychoacoustic validation is a defining characteristic of modern studies of the human HRTF (Wightman, F. L. and Kistler, D. J., 1989b).

The ability to measure and validate the HRTF in the same subject places a premium on efficient recording procedures. Most modern studies use a variant of the approach introduced by Mehrgardt S. and Mellert V. (1977), which replaces sinusoidal stimuli with pseudorandom noise. The spectrum of the noise is crafted using inverse Fourier transforms to have a broad bandwidth, random phase, and an amplitude spectrum that complements the output characteristics of the free-field speaker. The duration of the stimulus is made as short as possible to allow repetitive presentations from the free-field source while sound energy is recorded in the ear canal with a probe microphone. Averaging the microphone response across hundreds of presentations increases signal-to-noise ratios by lowering the noise floor of the recording. Consequently, deep spectral notches may be observed at low stimulus levels without eliciting middle ear reflexes that change the resonant properties of the ear canal. The Fourier transform of the averaged microphone response is divided by the Fourier transform of the noise burst to estimate the transfer function of the ear.

Figure 2 compares a modern description of the human HRTF (Wightman, F. L. and Kistler, D. J., 1989a), with representative results from three earlier studies (Mehrgardt, S. and Mellert, V., 1977; Shaw, E. A. G., 1974b; Wiener, F. M. and Ross, D. A., 1946). The measures were recorded at a source location of 0° azimuth, 0° elevation. Data from Figure 1 have been replotted to illustrate the remarkable consistency of independent measures by early investigators. Although all of the functions show good agreement at lower frequencies, early measures deviate considerably from the modern HRTF at frequencies above 2.5 kHz. These discrepancies are due in part to the presence of a deep spectral notch at frequencies between 7 and 10 kHz that was not revealed by early recording procedures. Wightman F. L. and Kistler D. J. (1989a) noted similar differences in the high-frequency HRTF throughout the horizontal and median planes.

The individual HRTFs of three subjects are presented in Figure 3. These results were obtained at locations in the horizontal plane that ranged from in front of the observer (0° azimuth) to behind the observer (180° azimuth). Each panel compares the function of the right ear (solid line) and left ear (dashed line). The right ear is the near ear for the two lateral locations (45° and 135° azimuth). The functions have been partitioned at 2.5 kHz, which is

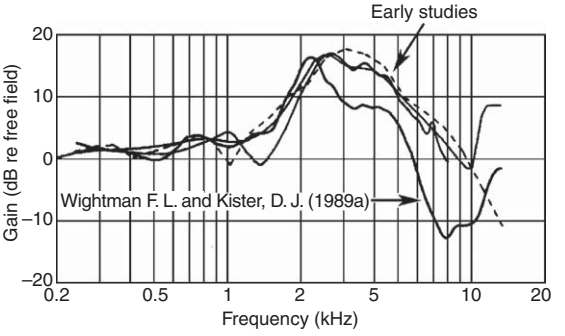

Figure 2 Comparison of early versus modern measures of the head-related transfer function at 0° azimuth, 0° elevation. The results of modern recording techniques are represented by Wightman F. L. and Kistler D. J. (1989a). Early measures are taken from Wiener and Ross (1946, solid bold line), Shaw (1974, light bold line), and Mehgardt and Mellert (1977, dashed line). Reused with permission from Wightman, F. L. and Kistler, D. J. The Journal of the Acoustical Society of America, 85, 858 (1989). Copyright 1989, Acoustical Society of America.

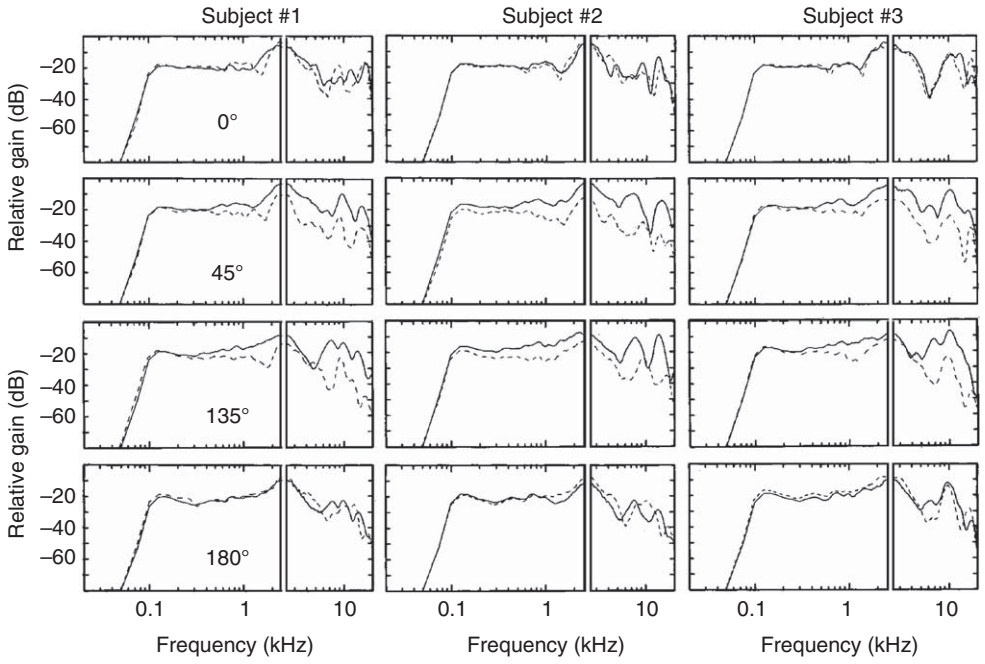

Figure 3 Comparison of individual head-related transfer functions (HRTFs) for three subjects at four locations in the horizontal plane. The solid curves indicate responses from right ears (near the speaker). The dashed curves are responses from left ears. Numerical labels indicate the azimuth of the sound source. The functions are separated at 5 kHz to emphasize intersubject differences in high-frequency spectral features. Adapted from Wightman, F. L., Kistler, D. J., and Perkins, M. E. 1987. A New Approach to the Study of Human Sound Localization. In: Directional Hearing (*eds.* W. A. Yost and G. Gourevitch). Springer: With kind permission of Springer Science and Business Media.

the frequency where the high-frequency measures of Wightman F. L. and Kistler D. J. (1989a) began to deviate from earlier recordings (Figure 2).

An examination of the low-frequency transfer functions verifies basic observations that were made more than 40 years earlier by Wiener F. M. and Ross D. A. (1946). The gain profile of each function rises to a maximum near 2.5 kHz, is higher in the near ear for lateral locations in the horizontal plane, and shows little variation between subjects.

The high-frequency transfer functions in Figure 3 reveal a very different pattern of localization cues. Here, the functions are marked by sharp spectral peaks and deep notches. On average, head-shadowing effects become more pronounced and yield larger ILD cues. At some frequencies, contradictory ILD cues are created by the presence of a spectral notch in the near ear or a spectral peak in the far ear. Individuals show clear differences in the frequency, shape, and magnitude of the spectral features.

Wightman F. L. and Kistler D. J. (1989b) obtained psychophysical validation of their acoustic measures by asking subjects to localize noise bursts that were presented under free-field conditions and with headphones. The latter stimuli were shaped by the HRTF of the free-field locations. Veridical simulations and actual locations are expected to elicit identical percepts. Figure 4 presents results from two subjects, with best and worst performances.

The scatterplots in Figure 4 contrast the target position of the stimulus with the judged position of the observer. Free-field responses are shown in Figure 4(a) and simulations in Figure 4(b). In the case of headphone stimuli, target position refers to the source location for the HRTF that was used in the simulation. A perfect correlation between stimulus and response ($r = 1$) is indicated by the unity line. Responses at six elevations are combined at each azimuth. Twenty-four azimuths are combined at each elevation.

Localization accuracy was excellent in the azimuth dimension of free-field responses. Statistical tests indicated a strong correlation between the judged positions and target positions of both subjects ($r > 0.98$). The errors generated by headphone stimuli only slightly exceeded those for natural sounds ($r > 0.97$). These results depict a best-case scenario

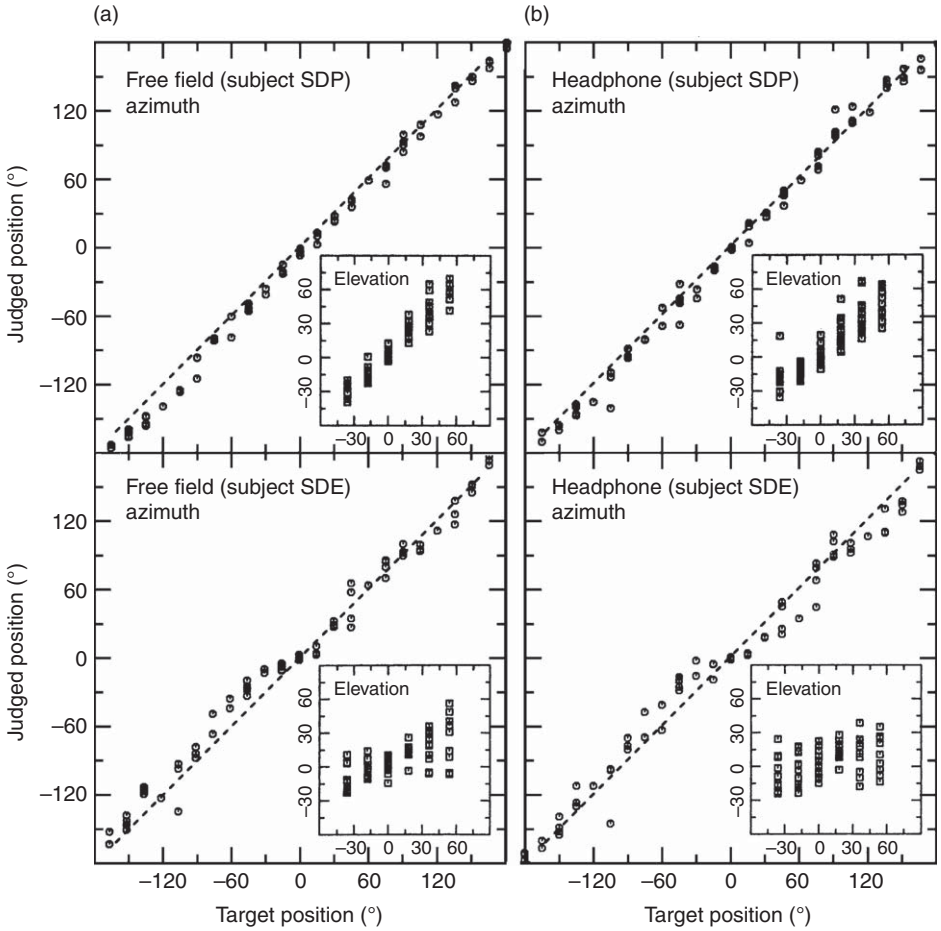

Figure 4 Comparison of free-field (a) and headphone (b) localization for two subjects. Judged positions are related to the azimuth of target positions in the main panels. Correct responses fall along the dashed line. The target positions of headphone stimuli indicate source locations during HRTF recordings. Inset: Responses to the elevation of target positions. Reused with permission from Wightman, F. L. and Kistler, D. J. The Journal of the Acoustical Society of America, 85, 858 (1989). Copyright 1989, Acoustical Society of America, 1989b.

where source location is derived from redundant ILD, ITD, and spectral cues. When these cues are placed in conflict, the azimuth directionality of a VSF stimulus is dominated by low-frequency ITDs (Wightman, F. L. and Kistler, D. J., 1992).

A missing detail in Figure 4 is the occurrence of front–back confusions; that is, the attribution of a front-hemisphere location to the back-hemisphere, or the less common opposite impression. To facilitate the comparison of free-field versus headphone performance, these potentially large errors have been removed by reflecting the data around the vertical axis to the correct hemisphere. Both subjects exhibited a greater tendency to make front–back confusions under closed-field conditions. The errors of subject SDP increased from three in free field to six with headphones. Subject SDE made substantially more of these errors in free field than SDP (12 confusions), and also displayed a loss of performance when tested with headphones (20 confusions).

Bandwidth manipulations of free-field stimuli suggest that front–back confusions are resolved by monaural spectral cues (Blauert, J., 1969/1970; Oldfield, S. R. and Parker, S. P., 1986). Because these cues are essential for localization in the median plane, the prevalence of confusion errors in the azimuth data of subject SDE predicts poor performance in the elevation dimension of localization responses. These results are presented in the inset panels of Figure 4.

Both subjects displayed elevation responses that were less accurate and more variable than their azimuth responses. The stimulus–response correlation

of subject SDP decreased slightly in free field (0.96), but showed a more precipitous drop under closed-field conditions (0.88). As predicted, subject SDE was especially challenged by this dimension of the task. Responses were poorly correlated in free field (0.68) and with headphones (0.43).

The increase of elevation errors for synthetic HRTFs suggests that the simulations failed to capture the full complement of spectral features that contribute to vertical sound localization. Notwithstanding the limitations of modern synthesis techniques, it is apparent that the high-frequency HRTF is highly individualized. Human subjects may display informative (SDP) or impoverished (SDE) localization cues under normal listening conditions (Middlebrooks, J. C., 1999a; Wenzel, E. M. *et al*., 1993).

3.37.5 Directional Transfer Functions

HRTFs provide a detailed description of outer ear acoustics. They do not reveal what acoustic features are influenced by changes in sound source direction and therefore provide veridical localization cues. The DTF is the spectral shape that remains after common nondirectional components of the HRTF are removed by statistical methods (Middlebrooks, J. C. and Green, D. M., 1990). This analysis provides a useful link between the quality of directional information and the accuracy of perceptual behavior (Middlebrooks, J. C.,1992).

Middlebrooks J. C. and Green D. M. (1990) recorded ear canal responses at hundreds of loudspeaker locations evenly distributed around the observer. Their methods for averaging microphone responses to noise bursts and converting the time domain signal into the frequency domain were essentially the same as those used by (Mehrgardt, S. and Mellert, V., 1977). Figure 5(a) presents two unprocessed magnitude spectra for recordings at 0° azimuth, 0° elevation. The responses were simultaneously recorded from the same ear with two probe microphones.

Dividing the spectral shapes in Figure 5(a) by the spectrum of the noise burst is expected to yield HRTFs that are equivalent to results from Wightman F. L. and Kistler D. J. (1989a) in Figure 2(a). Middlebrooks J. C. and Green D. M. (1990) argued that the HRTF is the product of the desired DTF and an unknown common transfer function that can be estimated by averaging the microphone response across all sampled locations. Thus, the DTF can be calculated by dividing the microphone responses in Figure 5(a) by the stimulus spectrum and the common transfer function.

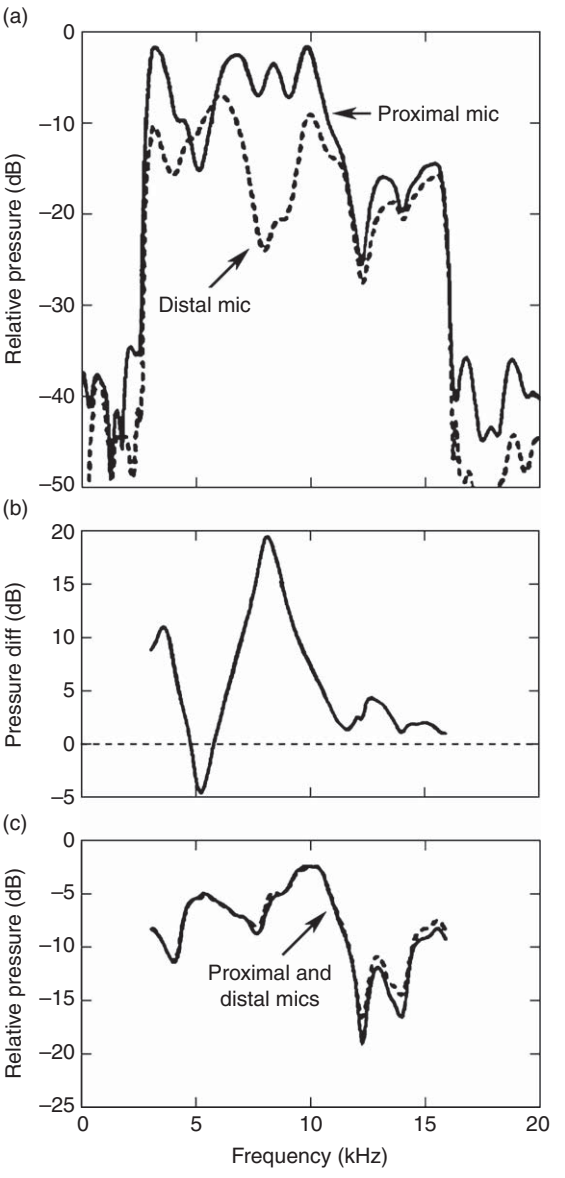

Figure 5 Directional transfer functions measured at proximal and distal locations in the ear canal. (a) Unprocessed magnitude spectra of responses to noise bursts. The responses were measured simultaneously with a 9 mm microphone separation. The sound source was located at 0° azimuth, 0° elevation. (b) Sound pressure differences between the two recordings. (c) Directional transfer functions derived by dividing the microphone responses by the stimulus spectrum and the common transfer function. Reused with permission from Middlebrooks, J. C. and Green, D. M. The Journal of the Acoustical Society of America, 87, 2149 (1990). Copyright 1990, Acoustical Society of America.

Figure 5(b) illustrates how placement can alter acoustic measures. Approximately 9 mm separate the proximal and distal microphones. The unprocessed magnitude spectra differ by as much as 24 dB between the recording sites. These pressure differences are produced by standing waves in the ear canal that may cancel or amplify select wavelengths according to insertion depth. These artifacts persist when microphone responses are converted to HRTFs.

Figure 5(c) compares the results of DTF calculations for the two recordings. Despite the large pressure differences in the raw magnitude spectra, the transfer functions are virtually identical. The ear canal resonances that give rise to standing waves are sensitive to microphone placement, but they are not affected by changes in source location. Consequently, this nondirectional component of the microphone signal is removed as part of the common transfer function.

Unlike the deep spectral notch in the HRTF of Wightman F. L. and Kistler D. J. (Figure 2), the DTF reveals a prominent spectral peak at frequencies between 7 and 10 kHz. The differences suggest that most transfer functions have the spectral notch, but it is less pronounced at frontal locations (0° azimuth, 0° elevation). As described later, these so-called covert peaks can exert profound effects on sound localization (Musicant, A. D. and Butler, R. A., 1984b).

3.37.5.1 Peripheral Coding of Monaural Localization Cues

The mechanical properties of the peripheral auditory system decompose the HRTF shape into its constituent frequency components (for general reviews of the auditory coding of complex sounds, see Evans, E. F., 1992; Lopez-Proveda, E. A., 2005). These elements are arrayed along the cochlear partition in a frequency dependent manner that establishes the first principle of auditory coding, the frequency to place transformation known as tonotopy (Narayan, S. S. *et al.*, 1998; Ruggero, M. A. *et al.*, 2000). Auditory-nerve fibers make spatially restricted synaptic contact with the tonotopic axis, and therefore respond selectively to a limited frequency range of the HRTF spectrum (Kim, D. O. and Molnar, C. E., 1979). Consequently, spectral cues for sound localization must be encoded by multiple fibers with complementary tuning properties. Fibers that are tuned to high-energy spectral peaks show high discharge rates and fibers that are tuned to spectral notches show low rates (Sachs, M. B. and Young, E. D., 1979).

3.37.5.2 Representation by the Rate Profiles of Auditory-Nerve Fibers

The representation of HRTF-based spectral shapes has been measured by recording the discharge rates of populations of auditory-nerve fibers in domestic cats (Poon, P. W. and Brugge, J. F., 1993; Rice, J. J. *et al.*, 1995). The localization behaviors of this predatory species is strongly influenced by directional properties of notches that are observed at mid frequencies of the HRTF (Musicant, A. D. *et al.*, 1990; Phillips, D. P. *et al.*, 1982; Rice, J. J. *et al.*, 1992). Examples of two HRTFs are shown in Figure 6(a). The locations that produced the HRTFs differed slightly in elevation. As the sound source changed in elevation, the spectral notch changed in frequency. Similar patterns have been observed for the outer ear acoustics of humans (Bloom, P. J., 1977; Butler, R. A. and Belendiuk, K., 1977).

The directional dependence of the mid-frequency notch causes the amplitude spectra of the two stimuli to diverge at frequencies between 10 and 20 kHz. These localization cues are illustrated in Figure 6(b) by plotting the level difference between the two HRTFs. Auditory-nerve fibers respond to these level differences with increases and decreases of discharge rate.

3.37.5.3 Modeling the Auditory-Nerve Representation of Monaural Spectral Cues

Quantitative descriptions of the peripheral representation of HRTF-based spectral shapes are facilitated by the largely homogeneous discharge properties of the auditory nerve. Figure 6(c) plots the rate differences that were observed when a population of auditory-nerve fibers was tested with the two HRTFs. The frequency location of each data point indicates the fiber's best frequency (BF: the most sensitive frequency). The magnitude of the level difference between the two stimuli is superimposed on the rate difference profile to emphasize the straightforward relationship between rate and level.

The effect of spectrum level on the auditory nerve is strikingly linear (May, B. J. and Huang, A. Y., 1997). This relationship is revealed in Figure 7 by plotting discharge rates in terms of the magnitude of the

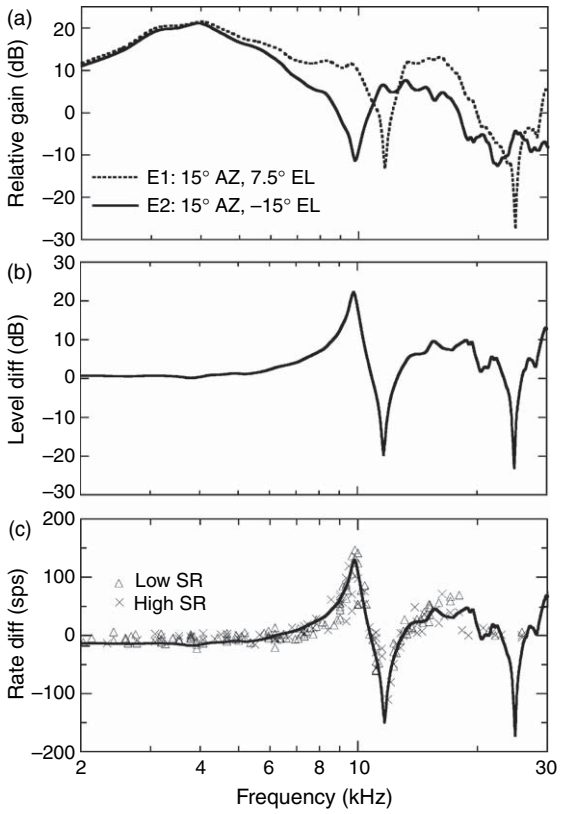

Figure 6 The auditory-nerve representation of the head-related transfer function (HRTF). (a). The relative gain of the cat's HRTF at two elevations. As the source moves from a negative elevation (E2) to a positive elevation (E1), the prominent mid-frequency notch moves to a higher frequency. (b). The level difference contour created by subtracting E2 from E1. Major directional effects are related to changes in the frequencies of spectral notches. (c). The rate differences of auditory responses to the two HRTFs. Each symbol is the E1–E2 rate difference for a single fiber, which is plotted at the fiber's BF. Different symbols distinguish fibers with high versus low spontaneous rates (SRs). The E1–E2 level contour is superimposed on the population response to emphasize the close correspondence between stimulus features and discharge rates. Reused with permission from May, B. J. and Huang, A. Y. The Journal of the Acoustical Society of America, 101, 2705 (1997). Copyright 1997, Acoustical Society of America.

amplitude difference at each fiber's BF. Fibers with high spontaneous rates produce a steeply sloped function, which indicates the neuron's robust representation of spectral peaks and notches (Figure 7(a)). Fibers with low spontaneous rates exhibit smaller differences because they are less sensitive to moderate sound levels (Figure 7(b)). The fibers play a critical role in the coding of spectral information at high sound levels and in the presence of background noise (Le Prell, G. S. *et al.*, 1996).

The quality of a neural code depends not only on response magnitude but also the variability of responses under identical stimulus conditions. Conveniently, the average SD of auditory-nerve discharge rates is proportional to the magnitude of sound-driven activity and is well fit by the power function in Figure 7(c).

Implicit in the linear rate–level relationship is the potential to model the auditory-nerve representation under conditions that simulate localization behavior (May, B. J. *et al.*, 1996; May, B. J. and Huang, A. Y., 1997). Because the relationship is linear, HRTF gain can be translated to a predicted discharge rate by a simple respecification of the amplitude axis. The simulated rates in Figure 8(a) are based on the rate–level relationship of high SR fibers (Figure 7(a)).

The two HRTFs used in the simulation re-create a change in lateral location. The sound source begins at a reference location directly in front of the subject and shifts to a positive (rightward) azimuth of 45°. Because the response of the right ear is being modeled, the sound takes a more direct route to the ear when it originates from the positive azimuth and the movement is associated with a frequency dependent gain (Calford, M. B. and Pettigrew, J. D., 1984). Level differences between the reference and comparison locations are reflected by positive discharge rates at the BF of most model fibers. The exception is a sharp rate decrease where the comparison HRTF displays its mid-frequency notch.

The rate profile may be expressed in terms of d' statistics to evaluate the information content of the simulated population response (Delgutte, B., 1989; Green, D. M. and Swets, J. A., 1974). This signal detection analysis specifies rate differences in units of SD. The d' statistics in Figure 8(b) were derived by dividing the simulated rates in Figure 8(a) by the SD values in Figure 7(c). By convention, the detection of an acoustic event is assumed when d' scores are greater than 1 or less than -1 (i.e., ± 1 SD). These frequency regions have been highlighted with shading to emphasize the potential physiological salience of the change in location.

The acuity of directional hearing is defined by the minimum audible angle (MAA) (Mills, A. W., 1958). This psychophysical threshold represents the just-detectable change in location relative to a reference that is usually directly in front of the observer (0° azimuth, 0° elevation). The comparison source locations are arranged in the horizontal plane to

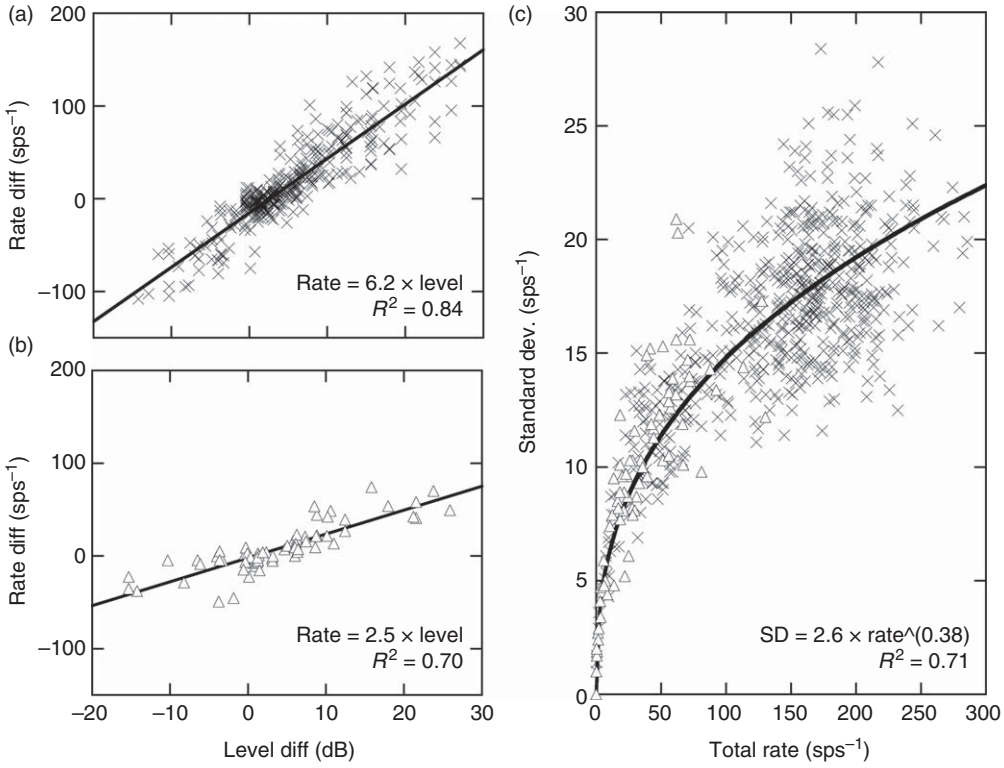

Figure 7 Statistical descriptions of the auditory-nerve representation of the head-related transfer function (HRTF). (a). The rate differences of high spontaneous rate (SR) auditory-nerve fibers for pairwise combinations of HRTF stimuli. Discharge rates are linearly related to the magnitude of the level difference at the fiber's BF. (b) Same relationship for low SR fibers. (c) The SD of discharge rates in the auditory nerve. SD was calculated from multiple presentations of the same stimulus. It increased with rate magnitude and was well fit by a power function. Reused with permission from May, B. J. and Huang, A. Y. The Journal of the Acoustical Society of America, 101, 2705 (1997). Copyright 1997, Acoustical Society of America.

determine the smallest detectable change in azimuth, or in the median vertical plane to determine the threshold for elevation.

The simulated d' values in Figure 9 compare the quality of localization cues at ten locations in the horizontal plane (15° increments) and at 16 locations in the median plane (7.5° increments). To incorporate the design of a minimum audible angle task, the d' statistic represents the magnitude of the rate differences between the set of comparison HRTFs and the fixed reference HRTF (0° azimuth, 0° elevation). In Figure 9(a), the most noticeable source of azimuth information is a systematic increase in the magnitude of d' as the comparison HRTF becomes more lateralized. Sounds originating at negative (leftward) azimuths are attenuated by the sound shadow of head, while sounds at positive (rightward) azimuth are amplified by the *acoustic fovea*. Acoustic differences between symmetrical positive and negative azimuths are equivalent to the binaural ILD cues reaching the two ears from a single lateralized location.

The head's sound shadow is less obvious in the median plane. Nevertheless, as shown in Figure 9(b), changes in elevation also produce systematic rate differences when the sound source moves from the reference location to positive (high) or negative (low) elevations. Unlike changes in azimuth, these localization cues tend to be less uniform, smaller in magnitude, and restricted to high frequencies (>6 kHz).

The broadly distributed rate increases that extend across positive azimuths and elevations are marked by a sharp negativity at frequencies between 10 and 20 kHz. The paradoxical rate decrease is created by the mid-frequency notch in the cat's HRTF. Although most frequencies are amplified by the HRTF, this select frequency range is attenuated to levels below the reference HRTF. The frequency of the notch displays a continuous increase as the sound

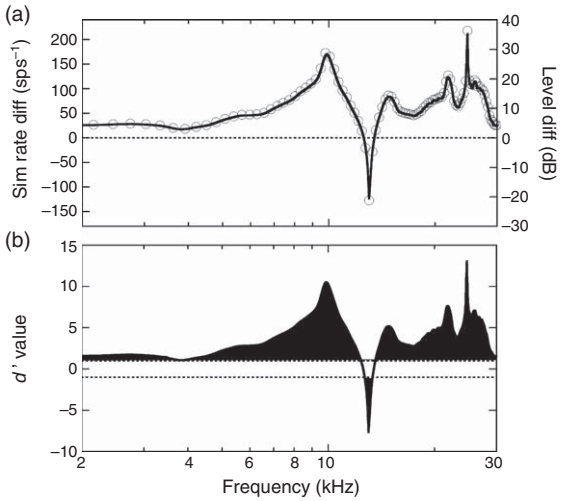

Figure 8 Simulated auditory-nerve responses to two HRTFs in the horizontal plane. (a). The level difference contour (line, right ordinate) was created by subtracting a reference HRTF (0° azimuth, 0° elevation) from a more lateralized comparison HRTF (45° azimuth, 0° elevation). The higher gain of the comparison HRTF is reflected in positive level differences. Simulated high SR discharge rates (symbols, left ordinate) were derived by applying the statistics in Figure 7(a) to rate differences. Because the rate–level relationship is linear, the simulated rate profile is identical to the level profile. (b) The simulated auditory-nerve response has been further transformed into the d' index of sensitivity by standardizing the magnitude of the rate difference. The SDs used in this calculation are taken from Figure 7(c). The information content of simulated discharge rates is indicated by shading regions where d' values are greater than 1 (black) or less than –1 (gray). Reused with permission from May, B. J. and Huang, A. Y. The Journal of the Acoustical Society of America, 101, 2705 (1997). Copyright 1997, Acoustical Society of America.

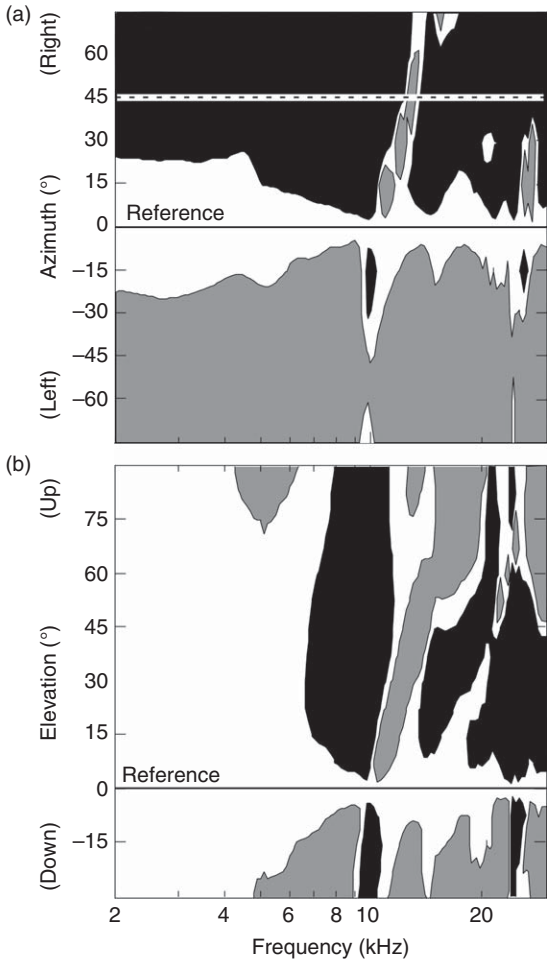

Figure 9 Simulated auditory-nerve responses in a minimum audible angle task. (a). Rate differences were calculated by applying the linear model to level differences between the reference HRTF (0° azimuth, 0° elevation) and 10 comparison HRTFs that were arrayed at 15° intervals along the horizontal plane. Regions where d' values are greater than 1 or less than −1 are indicated with black and gray shading, respectively. The d' contour in Figure 8(b) is indicated by the dashed line. (b). The same analysis for 16 elevations in the median plane. Reused with permission from May, B. J. and Huang, A. Y. The Journal of the Acoustical Society of America, 101, 2705 (1997). source moves from the reference location to more lateralized azimuths in the right hemifield or higher elevations in the median plane. The unambiguous association between frequency and location suggests that accurate sound localization may be achieved by combining rate information at the same frequency across ears (i.e., binaural processing of ILDs) or across frequencies at the same ear (i.e., monaural processing of spectral cues).

The magnitude of d' in the MAA simulation suggests that strong localization cues are communicated by high frequencies of the HRTF. This prediction has been verified by training cats to release a lever when a sound source changed from a reference location in front of the subject to a comparison location at a positive azimuth or elevation (Huang, A. Y. and May, B. J., 1996b). Best performance was observed with bursts of broadband noise or high-pass noise (>20 kHz).

3.37.5.4 Distinguishing Sound Localization and Directional Acuity

Distinctions between sound localization and spatial discrimination (e.g., the MAA task) have been noted

since the earliest psychophysical assessments of human directional hearing (Mills, A. W., 1958; Starch, D., 1908). A subject is only required to respond to acoustic differences that are correlated with directional changes. The subject may perceive change without absolute knowledge of the locations that contribute to the effect. In the context of directional acuity, a mid-frequency notch exerts less impact on the auditory-nerve population response because it is more localized in frequency and smaller in magnitude than the complex spectral variations found at high frequencies of the HRTF. The singularity of the notch does not lessen its importance in situations where the absolute location of the sound source must be determined (Hebrank, J. and Wright, D., 1974; Butler, R. A. and Belenduik, K., 1977; Bloom, P. J., 1977).

The ability to localize a discrete acoustic event implies that the auditory system can derive the absolute directionality of a sound source from physical characteristics of the HRTF. This process requires some unique directional property that distinguishes each HRTF from all other HRTFs. In Figure 10(a), the acoustic basis of absolute sound localization is explored by comparing an individual HRTF (0° azimuth, 0° elevation) to the statistical distribution of HRTF gains at over a 150 locations in the frontal sound field. Absolute localization cues are defined as spectral features that fall beyond the average HRTF shape by at least one SD. This statistical analysis emphasizes the unique directionality of spectral features in the same way as DTFs (Middlebrooks, J. C. and Green, D. M., 1991; Musicant, A. D. and Butler, R. A., 1984b). In this context, high-frequency cues are rendered less salient by a frequency-dependent increase in variability between HRTFs. The mid-frequency notch is the only feature that consistently extends beyond the ±1 SD criterion.

Figures 10(b) and 10(c) simulate the auditory-nerve representation of absolute sound localization cues. This analysis involves identifying frequencies where individual HRTFs deviate from the average HRTF by at least one SD, calculating the magnitude of the level difference relative to the SD boundary, and transforming the level difference into discharge rate with the linear model. The resulting d' statistics suggest a critical role for mid-frequency spectral notches. They are the only cue available for central locations in the horizontal and median planes, where cats show their most accurate sound localization behaviors (Populin, L. C. and Yin, T. C., 1998a; 1998b).

Predictions of the absolute localization model have been tested by measuring the cat's ability to

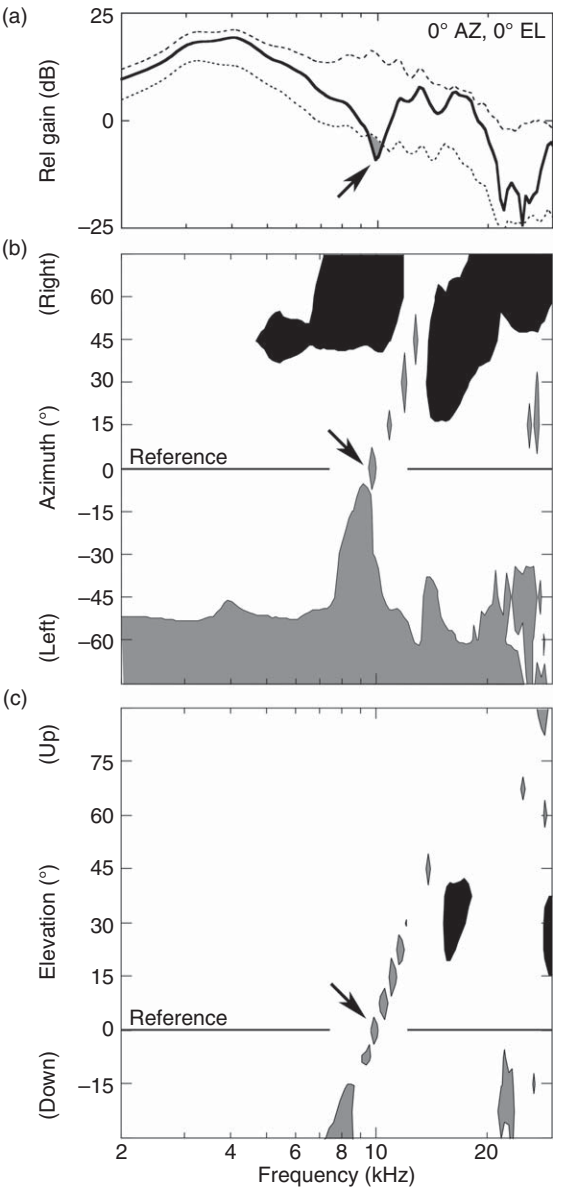

Figure 10 Simulated auditory-nerve responses in an absolute localization task. (a) Comparison of an individual HRTF (0° azimuth, 0° elevation) to the statistical distribution of HRTF gains at 179 locations in the frontal sound field. Dashed lines indicate ±1 SD relative to the mean of the distribution. The mid-frequency spectral notch where the HRTF falls below −1 SD is indicated by gray shading (arrow). (b) Simulated d' values based on the magnitude of individual HRTFs relative to SD contours. Rate responses to the HRTF at 0° azimuth, 0° elevation is indicated by the line. The arrow points to the statistically significant rate decrease at the mid-frequency spectral notch. Additional plotting conventions are described in Figure 9. (c) Same analysis for 16 elevations in the median plane. Reused with permission from May, B. J. and Huang, A. Y. The Journal of the Acoustical Society of America, 101, 2705 (1997). orient to discrete sound presentations (May, B. J. and Huang, A. Y., 1996). Cats make this natural reflexive behavior with very little training (Sutherland, D. P. *et al.*, 1998b). If the bandwidth of the orientation stimulus is modified in a manner that conserves mid-frequency spectral information, accurate behavior is maintained. Limiting the sound spectrum to high frequencies elicits poorly directed head movements (Huang, A. Y. and May, B. J., 1996a).

3.37.6 Pathways of the Dorsal Cochlear Nucleus and Inferior Colliculus

The central nervous system is known for its remarkable diversity of anatomical and physiological adaptations for encoding binaural directional information. Monaural localization cues also play an important role in the biological world of most mammalian species and there is good evidence that the auditory system has developed similar specializations to ensure efficient spectral processing. When the auditory-nerve representation of spectral cues for sound localization enters the brain, the dorsal cochlear nucleus (DCN) integrates this ascending input to create a neuron that is sensitive to the sharp spectral features of HRTF-shaped sounds (Oertel, D. and Young, E. D., 2004). Ascending projections from the DCN bypass the binaural brainstem and climb directly to the central nucleus of the ICC where monaural spectral representations are further transformed to enhance spatial selectivity.

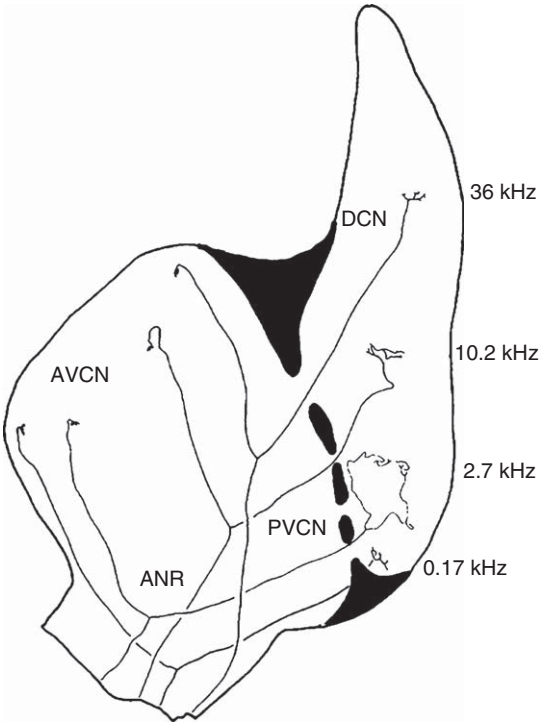

Figure 11 Drawing tube reconstruction of the central processes of four auditory-nerve fibers. Frequency tuning characteristics were measured electrophysiologically before intracellular labeling with horseradish peroxidase. Numerical labels indicate BF. Descending projections pass through the posteroventral cochlear nucleus to terminate in a tonotopically organized manner in the dorsal cochlear nucleus. ANR, auditory-nerve root; AVCN, anteroventral cochlear nucleus; DCN, dorsal cochlear nucleus; PVCN, posteroventral cochlear nucleus. Reproduced from Ryugo, D. K. and Parks, T. N. Primary innervation of the avian and mammalian cochlear nucleus. Brain Res. Bull. 60, 435–456. Copyright (2003), with permission from Elsevier.

3.37.6.1 Dorsal Cochlear Nucleus

The central projections of the auditory nerve bifurcate upon entering the cochlear nucleus to send an ascending branch to the anteroventral subdivision and a descending branch to the posteroventral and dorsal subdivisions (Lorente De Nó, R., 1933; Ryugo, D. K. and Parks, T. N., 2003). The highly structured topography of these projects is shown in Figure 11. Fibers from the low-frequency apex of the cochlea terminate in the ventral DCN, while fibers from the high-frequency base terminate dorsally. As a result, the tonotopic organization of the cochlea is transferred to the brainstem (Spirou, G. A. *et al.*, 1993). It is common for central auditory nuclei to exaggerate the tonotopic representation of functionally relevant frequencies. For example, the medial superior olive is primarily involved with low-frequency binaural temporal processing (Tsuchitani, C., 1977). The cat's DCN shows a similar bias for the mid-frequency sounds that convey important HRTF directional features (Spirou, G. A. *et al.*, 1993).

Auditory-nerve inputs to the DCN are modified by a complex intrinsic circuitry (for recent reviews, see Oertel, D. and Young, E. D., 2004; Young, E. D. and Davis, K. A., 2002). These largely inhibitory influences activate selectively under different conditions of stimulation. The hypothesized circuit is summarized by the simple model in Figure 12(b). The anatomical counterparts of the model are shown in Figure 12(a).

Before the excitatory inputs of the auditory nerve are relayed to the ICC by type-IV projection neurons (pyramidal cells), they are shaped by two sources of

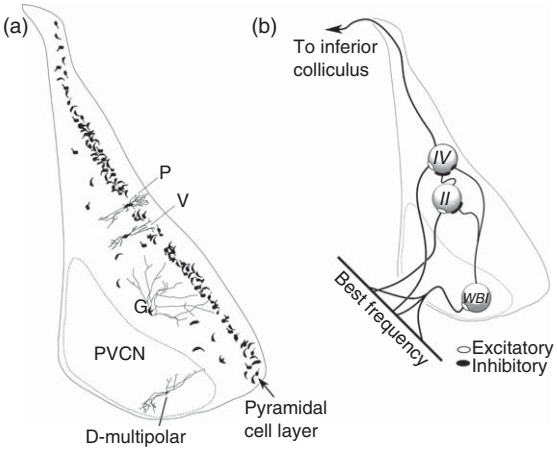

Figure 12 Summary of the functional anatomy of the DCN. (a) Principal anatomical cell types. Ascending projections originate from pyramidal (P) and giant cells (G). These responses are shaped by excitatory inputs from the auditory nerve (not shown) and inhibitory inputs from vertical cells (V) and D-multipolar cells. (b) Neural circuit model. The type-IV response pattern is assumed to arise from pyramidal or giant cells. Vertical neurons are a likely source of type-II inhibition. WBI is associated with inputs from D-multipolar cells. The excitatory tuning of the response types is indicated by the distribution of inputs along the BF axis. PVCN, posteroventral cochlear nucleus. Adapted from Young, E. D. and Davis, K. A., 2002. Circuitry and function of the dorsal cochlear nucleus. In: Integrative Functions in the Mammalian Auditory Pathway (*eds.* D. Oertel, R. R. Fay and Popper, A. N.), pp. 160–206. Figure 13 Responses of two DCN pauser neurons to free-field noise bursts. (a) Discharge rates evoked from one neuron (BF = 10 kHz) by sound sources in the horizontal plane. The magnitude of the response is expressed as a percentage of maximum (gray scale on right). The decrease in noise-driven rate at the −15° azimuth is explained by a mid-frequency null at the neuron's BF (arrow). (b) Responses of a second neuron (BF = 11 kHz) to sound sources at different azimuths and elevations in the frontal sound field. The predicted trajectory of an 11 kHz null (line) coincides with rate decreases. Reproduced from Imig, T. J., Bibikov, N. G., Poirier, P., and Samson, F. K., 2000. Directionality derived from pinna-cue spectral notches in cat dorsal cochlear nucleus. J Neurophysiol, 83, 907–925. Copyright (2000), used with permission from The American Physiological Society.

inhibition (Nelken, I. and Young, E. D., 1994). The frequency tuning of these inhibitory neurons is indicated by the distribution of connections on the BF axis of the model. The type-II inhibitory input to the type-IV unit is sharply tuned in frequency and tends to have a BF that is slightly lower than the type-IV neuron (Hancock, K. E. *et al.*, 1997). These responses have been attributed to vertical cells in the deep layers of the DCN (Spirou, G. A. *et al.*, 1999; Young, E. D. and Voigt, H. F., 1982). A second inhibitory input is weaker and more broadly tuned (Hancock, K. E. and Voigt, H. F., 1999; Nelken, I. and Young, E. D., 1994). Wide-band inhibition (WBI) is assumed to arise from multipolar cells in the posteroventral cochlear nucleus (Arnott, R. H. *et al.*, 2004; Doucet, J. R. *et al.*, 1999; Hancock, K. E. and Voigt, H. F., 1999; Nelken, I. and Young, E. D., 1996; Oertel, D. *et al.*, 1990).

The model predicts the output of the DCN under a variety of stimulus conditions. Type-IV units are weakly driven by broadband noise with a uniform amplitude spectrum because they are simultaneously excited by auditory-nerve inputs and inhibited by a combination of type-II and WBI inputs. Adding a directional notch to the noise spectrum may either potentiate or reduce the response. If energy is removed from frequencies that excite the type-II unit, the type-IV unit will be less inhibited. If energy is removed from frequencies that excite the type-IV unit, it will show stronger inhibitory responses. A spectral peak evokes the opposite pattern of responses.

The predicted notch sensitivity of type-IV units has been confirmed by the responses of DCN neurons to free-field stimuli (Imig, T. J. *et al.*, 2000). Figure 13(a) plots the responses of a pauser unit that was recorded in an anesthetized cat. This

temporal pattern is associated with type-IV activity in unanesthetized preparations (Pfeiffer, R. R., 1966). As the stimulus moves in the horizontal plane, the neuron's discharge rates capture the essential properties of the auditory-nerve population response (Figures 9(a) and 10(b)). Higher discharge rates are observed at positive (ipsilateral) azimuths, and lower discharge rates at negative (contralateral) azimuths. Minimum rates signal locations where spectral notches coincide with BF.

A more complete picture of the directional properties of the DCN is obtained by plotting discharge rates as a function of both azimuth and elevation. The responses of a second pauser neuron (BF = 11 kHz) are shown in Figure 13(b). A distinguishing feature of the neuron's spatial response map is the consistent rate decrease that follows the trajectory of an 11 kHz spectral notch (line). Because this notch frequency exists at multiple locations, rate decreases define a spatial contour and not a point in space (Rice, J. J. *et al.*, 1992). The representation of a specific location along the isonotch contour requires additional spectral processing. This more selective coding has been observed in the ICC (Davis, K. A., 2005).

3.37.6.2 Inferior Colliculus

It may be argued that the central nucleus of the ICC is an obligatory relay for the ascending projections of the auditory brainstem (Aitkin, L. M. and Phillips, S. C., 1984). Although these pathways converge within the midbrain (Adams, J. C., 1979; Malmierca, M. S. *et al.*, 2005; Oliver, D. L. *et al.*, 1997), ICC neurons exhibit physiological properties that appear to be dominated by discrete sources of input under certain conditions of stimulation (Davis, K. A. *et al.*, 1999; Ramachandran, R. *et al.*, 1999). The directional sensitivity of the resulting physiological response types may be influenced by binaural processes that are performed in the superior olive or by monaural spectral cues that encoded by the DCN (Davis, K. A., 2002; Ramachandran, R. and May, B. J., 2002).

A number of studies have characterized the spatial tuning of ICC neurons with free-field stimuli (Aitkin, L. M. *et al.*, 1984; Bock, G. R. and Webster, W. R., 1974; Leiman, A. L. and Hafter, E. R., 1972; Moore, D. R. *et al.*, 1984; Semple, M. N. *et al.*, 1983). Much of this work has focused on responses to pure tones in the horizontal plane. Under these restricted testing conditions, spatial selectivity is strongly influenced by the binaural processing of interaural time and level differences (Aitkin, L. M. and Martin, R. L., 1987; Aitkin, L. M. *et al.*, 1985). Nevertheless, an enhanced directional selectivity is observed when neurons are tested with broadband sounds containing HRTF-based spectral cues (Poirier, P. *et al.*, 2003).

The specific contributions of spectral cues for sound localization are potentially isolated by measuring the responses of ICC neurons to changes in the elevation of free-field sounds. As in studies of horizontal acuity, these experiments typically involve sound sources that are restricted to a single plane. In this case, it is the median vertical plane.

The cat's HRTF does not show sharp spectral filtering at low frequencies, so it is not surprising that elevation sensitivity is limited to neurons with BFs above 6 kHz (Aitkin, L. M. and Martin, R. L., 1990). An unexpected observation is that the spatial tuning is similar for azimuth and elevation and can be induced with both broadband and tonal stimuli. Examples of these measures are shown in Figure 14.

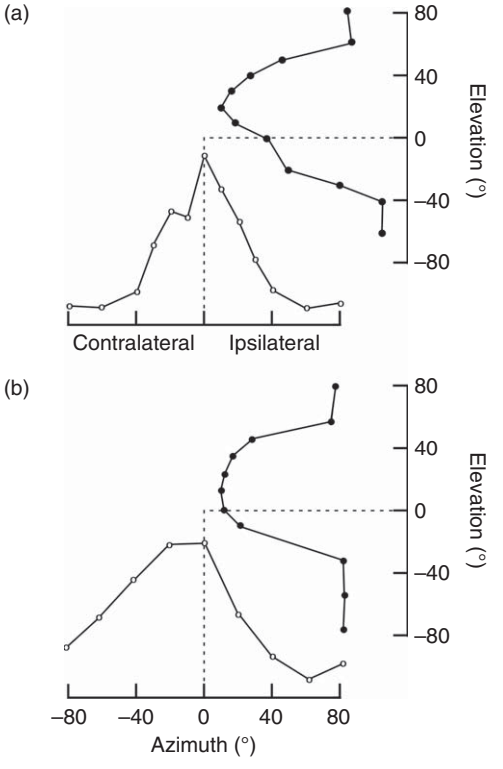

Figure 14 Responses of two ICC neurons to free-field sounds. (a) Unit showing spatial tuning for both azimuth and elevation when tested with noise bursts. (b) Unit showing similar tuning when tested with BF tones. The speaker array was fixed at an elevation of 40° for testing in azimuth and an azimuth of 0° for testing in elevation. Reproduced from Aitkin, L. and Martin, R., 1990. Neurons in the ICC of cats sensitive to sound-source elevation. Hear Res, 50, 97–105. Copyright (1990), with permission from Elsevier.

These results have led to the conclusion that elevation sensitivity may be partly mediated by the same binaural comparisons that dictate azimuthal sensitivity. It should be pointed out, however, that this method for defining the directionality of a neural response has the same shortcomings as the spatial discrimination procedure in Figure 9. Any acoustic change between sound sources has the capacity to modulate neural discharge rates. Consequently, spatially selective responses may reflect veridical localization cues or simple changes in sound pressure level that are given directional significance by the restricted spatial context in which they are examined. Well-established psychoacoustic effects argue against the accurate vertical localization of pure tones (Butler, R. A. and Planert, N., 1976).

The independent contributions of binaural and monaural localization processes have been studied in isolation with VSFs (Chase, S. M. and Young, E. D., 2006; Davis, K. A., 2005; Delgutte, B. *et al.*, 1999). This paradigm simulates a free-field environment under closed-field conditions by shaping broadband sounds with the directional properties of the HRTF. Individual localization cues may be modified, removed, or placed in competition with the remaining directional properties of the simulated sound source.

The VSF selectivity of ICC neurons recapitulates their responses to free-field stimuli (Delgutte, B. *et al.*, 1999). Examples of typical responses are shown in Figure 15. When ITD cues are removed from VSF stimuli and electrophysiological recording is restricted to neurons with best frequencies above 4 kHz, most neurons respond preferentially to contralateral azimuths, reflecting the strong excitatory input from the opposite ear. This tuning may encompass the contralateral field (Figure 15(a)) or rise to a peak at a best azimuth (Figure 15(b)). For the majority of azimuth sensitive neurons, directional tuning is sharpened by the binaural inhibitory interactions of the opposite ear and degrades under monaural testing conditions.

Binaural sensitivity is not an absolute prerequisite of azimuth sensitivity (Delgutte, B. *et al.*, 1999). The discharge rates of monaural neurons are also modulated by changes in the azimuth of VSF stimuli. As discussed before, this azimuth sensitivity may arise from the monaural processing of spectral cues or simple changes in the gain of the HRTF in the contralateral ear.

Approximately half of ICC neurons respond selectively to VSF elevations in the median plane

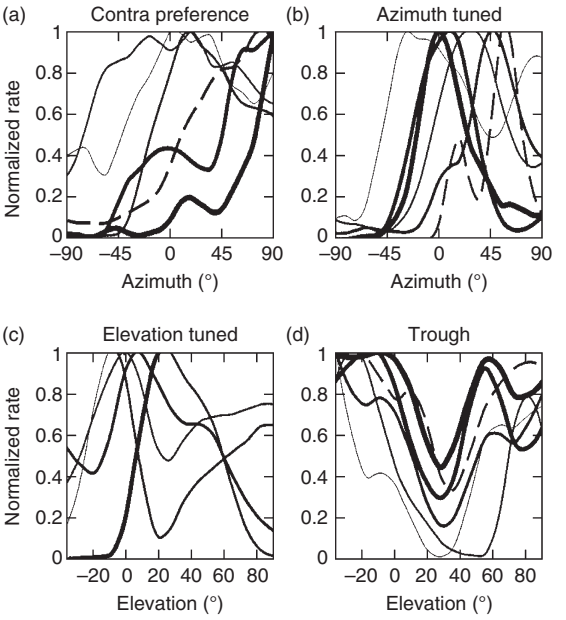

Figure 15 Responses of ICC neurons to VSF stimuli. (a, b) Examples of common azimuth tuning properties. (c, d) Common elevation tuning properties. Reproduced from Delgutte, B., Joris, P. X., Litovsky, R. Y., and Yin, T. C. 1999. Receptive fields and binaural interactions for virtual-space stimuli in the cat ICC. J. Neurophysiol. 81, 2833–2851., Copyright (1999), used with permission from The American Physiological Society.

(Delgutte, B. *et al.*, 1999). Unlike the results of earlier free-field experiments, many neurons with azimuth sensitivity fail to respond to changes in elevation. The neurons that do respond to these changes tend to display sharply tuned rate peaks (Figure 15(c) or troughs (Figure 15(d)). These strongly modulated responses imply a sensitivity to HRTF-based spectral peaks or notches, or combinations of both features in patterns that maximize excitatory inputs.

The dichotomy between azimuth and elevation sensitivity implies two modes of directional processing. A binaural mode imparts azimuth sensitivity through the interaction of contralateral excitatory and ipsilateral inhibitory inputs. A monaural mode modulates responses to changes in elevation or azimuth depending on the relationship between the tuning properties of the neuron and the directional properties of the HRTF. Neurons showing monaural sensitivity tend to have BFs that fall within the mid-frequency notch region of the HRTF.

ICC neurons can be linked to their brainstem inputs by shared response patterns (Davis, K. A.

et al., 1999; Ramachandran, R. *et al.*, 1999). Type-I neurons are distinguished by a frequency response map (FRM) with lateral inhibition (Figure 16(a)). As a result, excitatory tuning is restricted to an I-shaped region above the best-frequency threshold. The neurons are strongly inhibited when the frequency of a spectral notch coincides with BF and thus removes energy from the narrowly tuned excitatory field (Figure 16(b)). Similar inhibitory properties are displayed by the projection neurons of the lateral superior olive (LSO) implying that ascending projections from the binaural brainstem may preferentially target type-I units (Ramachandran, R. *et al.*, 2000).

Additional inferences regarding the ascending innervation of type-I units may be drawn from their binaural sensitivity and spatial selectivity (Davis, K. A. *et al.*, 1999; Ramachandran, R. *et al.*, 1999; Ramachandran, R. and May, B. J., 2002). Like LSO neurons, type-I units are excited when sounds are presented to the contralateral ear (E) and inhibited when sounds are presented to the ipsilateral ear (I). This so-called EI interaction is modulated by the timing of binaural stimulation. As demonstrated with closed-field stimuli in Figure 16(c), maximum ipsilateral inhibition is observed at a characteristic delay (CD) (Kuwada, S. *et al.*, 1987). The delay compensates for asymmetries of the binaural auditory system to deliver coincident inhibitory and excitatory inputs to the LSO (Batra, R. *et al.*, 1997). The requisite ITD is conferred under free-field conditions by the azimuth of the sound source.

The spatial tuning of type-I units is illustrated with a VSF procedure in Figure 16(d). As predicted by the EI binaural interaction, there is a sharp transition from excitatory to inhibitory responses as the simulated sound source moves from contralateral to ipsilateral locations. Although the responses of this unit were sampled across a broad range of azimuths

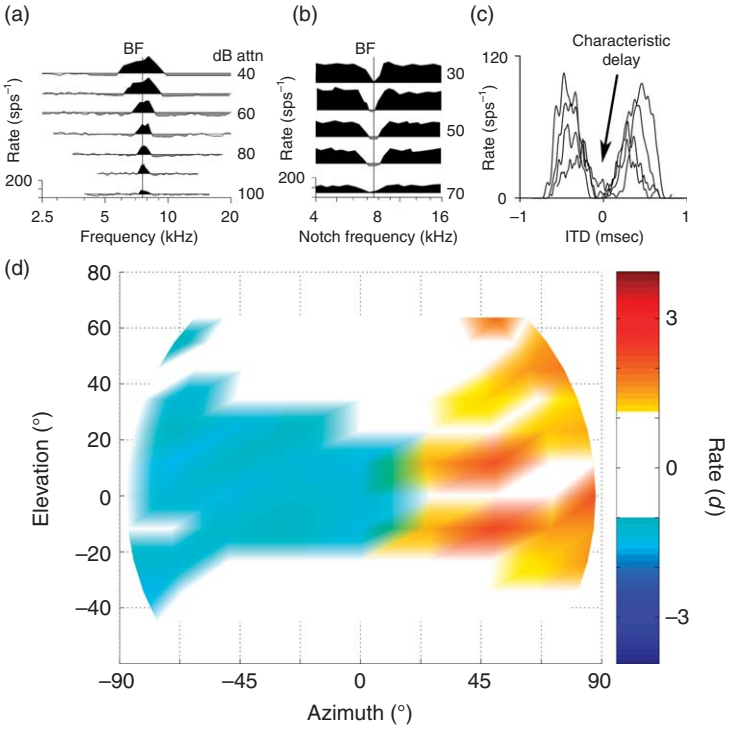

Figure 16 Physiological characteristics of ICC type-I units. (a) The narrow I-shaped excitatory tuning of the frequency response map (black) is dictated by lateral inhibition (gray). These inhibitory effects are potentiated when a spectral notch falls at BF (b) or binaural stimuli reach the two ears with a characteristic time delay (c). These response patterns are associated with the projection neurons of the lateral superior olive. (d) The binaural inhibitory properties of type-I units create contralateral preferences when the units are tested with VSF stimuli. Most units are excited by contralateral (positive) azimuths and inhibited by ipsilateral (negative) azimuths. Sound-driven rates are specified in units of SD relative to spontaneous activity (d'). Regions in red or blue represent statistically significant responses. Reproduced from Ramachandran, R. and May, B. J. 2002. Functional segregation of ITD sensitivity in the inferior colliculus of decerebrate cats. J. Neurophysiol. 88, 2251–2261. Copyright (2002), used with permission from The American Physiological Society.

and elevations, a subset of the stimulus conditions were arranged along the interaural horizontal axis (0° elevation) and therefore is equivalent to those shown in Figures 15(a) and 15(b). Under matching conditions, type-I units display the same directional properties as contra-preferring neurons. This spatial tuning is dictated by ILDs that are relatively unaffected by changes in elevation.

Type-O responses in the ICC are established by ascending projections from the DCN (Davis, K. A., 2002; 2005). As shown by the FRM in Figure 17(a), this response type takes its name from the O-shaped island of excitation that is consistently observed near the BF threshold (Ramachandran, R. *et al.*, 1999). In addition to sharing the strong on-BF inhibitory effects of DCN projection neurons, most type-O units show monaural responses when tested with ITD procedures (Figure 17(c)). They are silenced by surgical or pharmacological manipulations that disrupt the output pathways of the DCN (Davis, K. A., 2002).

Type-O units further transform the spectral integration properties of their DCN counterparts to optimize the processing of monaural localization cues (Davis, K. A. *et al.*, 2003). In Figure 17(b), the frequency of a spectral notch is swept across the receptive field of a type-O unit. Unlike the inhibitory responses that are observed for DCN type-IV units (Figure 8) or ICC type-I units (Figure 16(b)), type-O units exhibit strong excitatory responses at their characteristic notch frequency. This selectivity arises because a sharply tuned inhibitory input is turned off by the removal of spectral energy at frequencies near BF. When local GABAergic inhibition is blocked by administration of bicuculine, type-O units display the more generalized response patterns of type-IV and type-I units (Davis, K. A., 2002).

From a sound localization perspective, spectral selectivity is synonymous with spatial tuning. As shown in Figure 17(d), type-O units respond to the narrow range of azimuths and elevations where the HRTFs of VSF stimuli display the characteristic

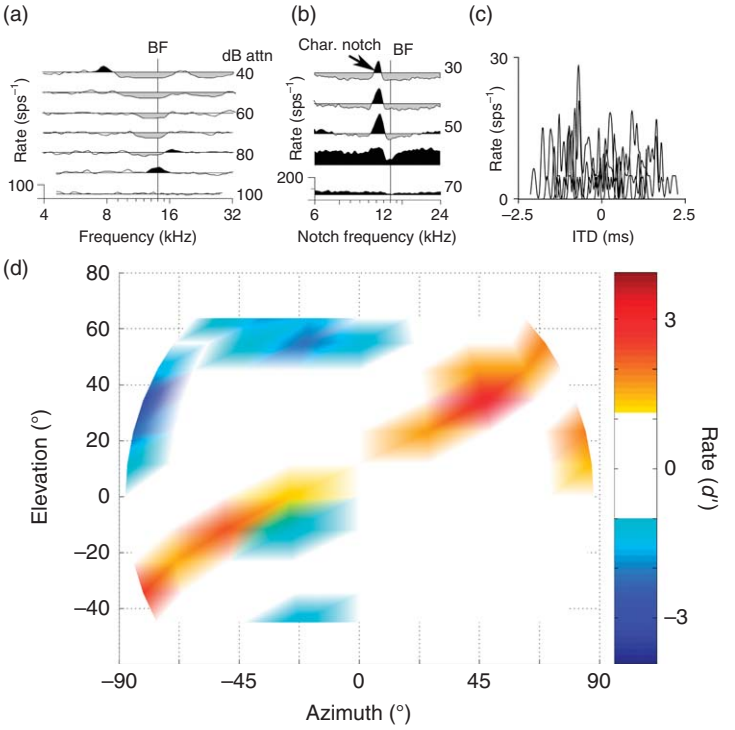

Figure 17 Physiological characteristics of ICC type-O units. (a) The frequency response map is largely inhibitory with the exception of an O-shaped island of excitation at the best-frequency threshold. The discharge rates of type-O units are strongly modulated when a spectral notch sweeps over BF (b) but most are insensitive to binaural cues (c). (d) Despite their lack of binaural sensitivity, the notch selectivity of type-O units tunes their excitatory responses to the azimuth and elevation of VSF stimuli. Plotting conventions are described in Figure 16. Reproduced from Ramachandran, R. and May, B. J., 2002. Functional segregation of ITD sensitivity in the inferior colliculus of decerebrate cats. J. Neurophysiol. 88, 2251–2261. Copyright (2003), used with permission from The American Physiological Society.

notch frequency. When responses are limited to a single horizontal or vertical plane, directional properties compare favorably with the tuned azimuth and elevation responses in Figures 15(b) and 15(c). Although these results were obtained with binaural stimuli, the weakly binaural type-O units are not significantly affected by the removal of ipsilateral stimulation.

Despite the discrete nature of ICC unit types, most neurons are sensitive to multiple sound localization cues (Chase, S. M. and Young, E. D., 2005). Chase S. M. and Young E. D. applied an information theory approach to discharge rates that were evoked by parametric manipulations of ITD, ILD, and spectral notches. The feature of interest was presented under closed field conditions and adjusted to conform to the frequency tuning characteristics and threshold of individual neurons. For example, in one series of experiments, the playback rate of HRTF stimuli was varied to sweep the mid-frequency spectral notch across BF. Under these conditions, type-I units provided the most information regarding changes in notch frequency and ILD.

An important distinction to be made with these findings is the unique role of auditory neurons that are generalists versus specialists. In the context of spectral cues for sound localization, these characteristics are synonymous with narrowband versus wideband integration. The lateral inhibitory properties of type-I units sharpen frequency tuning and endow the neurons with the ability to encode spectral peaks and notches (Ramachandran, R. *et al.*, 2000). These narrowband responses are sensitive to variations in the magnitude of local HRTF features but ignore the broader context in which they occur. As a result, the neurons show strongly modulated responses to notch frequency sweeps (Figure 16(b)) but little directional selectivity (Figure 16(c)). By contrast, the wideband integration properties of type-O units diminish their generalized spectral sensitivity, but maximize the selectivity of their spatial coding (Figure 17(c)).

3.37.7 Acoustic Manipulations of the Spectral Processing Pathway

In good agreement with physiological descriptions of the sound localization pathways, an extensive psychophysical literature suggests that binaural and monaural processes merge to support the accurate localization of sound source azimuth and elevation (for a general review of human psychophysical literature, see Middlebrooks, J. C. and Green, D. M., 1991). The relative importance of binaural and monaural pathways has been addressed by acoustic manipulations that alter the ear's input to the brain or the spectral content of the stimulus that impinges on the ear.

3.37.7.1 Altering the Ear's Input to the Brain

Complete unilateral deafness may be considered the most profound manipulation of the ear's input (Gatehouse, R. W., 1976). In parallel with Lord Rayleigh's (1907) classic treatise on the duplex theory of binaural sound localization, Angell and Fite (Angell, J. R. and Fite, W., 1901a; 1901b) introduced the concept of spectral based directional cues by describing the localization abilities of an individual who was profoundly deaf in one ear. Although localization was extremely uncertain in the region opposite the affected ear, the individual was able to make accurate responses to sound sources on the side of the intact ear. Sounds with increased spectral complexity were associated with faster and more accurate localization, which led these investigators to propose that directional quality is imparted by the frequency-dependent damping and reinforcement of sound energy by pinna acoustics. These observations have been confirmed in subsequent studies of unilateral deafness (Slattery, W. H., 3rd and Middlebrooks, J. C., 1994; Starch, D., 1908; Viehweg, R. and Campbell, R. A., 1960).

Prior to detailed descriptions of the human HRTF and the digital signal processing techniques that are required to synthesize these acoustic effects, Gardner M. B. and Gardner R. S. (1973) linked the directional properties of the pinna to sound localization by progressively occluding the ear cavities of human listeners. These simple, yet elegant experiments systematically related perceptual errors to the extent of occlusion, the location of the sound source, and the high-frequency content of the auditory stimulus. Their basic findings on the importance of pinna-based spectral cues in vertical localization have not been challenged by decades of ensuing research and more sophisticated testing procedures.

Other investigators have attempted to simulate monaural localization effects by completely plugging one ear of normal listeners (Oldfield, S. R. and Parker, S. P., 1986). These procedures are somewhat controversial because even low levels of sound in the occluded ear provide access to interaural localization

cues (Wightman, F. L. and Kistler, D. J., 1997). Noteworthy among these studies are experiments by Slattery W. H., 3rd and Middlebrooks J. C. (1994) that have explored the limitations of plugging procedures with direct comparisons of acute versus chronic unilateral deficits. Although there is considerable variation in the performance of individuals with congenital deafness in one ear, most subjects show the remarkably normal abilities that were observed by Angell J. R. and Fite W. (1901a; 1901b). By contrast, plugging one ear of normal listeners leads to the highly inaccurate perception of a sound source that is translated toward the unobstructed ear. The temporary distortion of binaural input has less effect on vertical localization. Two alternative conclusions may be drawn from the powerful immediate deficits of monaural plugging procedures. Spectral cues may play only a supportive role in horizontal localization (Batteau, D. W., 1967; Musicant, A. D. and Butler, R. A., 1984a), or their spatial attributes may be enhanced by the binaural processing of interaural spectral differences (Searle, C. L. *et al.*, 1975).

The clear differences in acute versus chronic manipulations suggest that ear plugs do not adequately unmask the full utility of monaural spectral cues (Jin, C. *et al.*, 2004). With sufficient experience, listeners can learn to rely exclusively on the directional properties of the pinna for the localization of both azimuth and elevation (Musicant, A. D. and Butler, R. A., 1980; Van Wanrooij, M. M. and Van Opstal, A. J., 2004). This compensation has also been observed when individuals are given sufficient time to adapt to the sound altering effects of ear cavity occlusion (Hofman, P. M. *et al.*, 1998; McPartland, J. L. *et al.*, 1997; Van Wanrooij, M. M. and Van Opstal, A. J., 2005) or supernormal localization cues (Shinn-Cunningham, B. G. *et al.*, 1998). From a clinical perspective, the effects of conductive hearing loss on sound localization show similar patterns of compensation in patients with chronic versus acute otitis media (Kawase, T. *et al.*, 1999).

3.37.7.2 Spectral Manipulations

An alternate strategy for characterizing the perceptual impact of monaural spectral cues is to manipulate the frequency content of the stimulus. In their simplest incarnation, these experiments can be traced to Pratt C. C. (1930), who noted that the frequency of a pure tone altered the spatial character of sound source elevation. Similar perceptual effects have been described for narrow bands of noise (Blauert, J., 1969/1970, 1997). For example, as the frequency content of a noise band changes from 1 to 5 kHz, the spatial attributes of the sound source shifts from behind to in front of the listener regardless of its actual angle of incidence. Acoustic measures indicate that these location judgments are correlated with a directional boost of the energy band. That is, the DTF exerts a high gain when frequencies near 4–5 kHz reaches the ear from a frontal location (Figure 5(c)). A rearward enhancement is noted at frequencies near 1–2 kHz.

A subtle property of Blauert's directional bands is that they are derived localization cues. That is, they are based on the relative acoustic differences that distinguish individual transfer functions from the average spectral shape of all transfer functions. Because they are not an absolute property of the transfer function, Musicant A. D. and Butler R. A. (1984b) have described these features as covert peaks.

Frequency also exerts strong effects on monaural localization in the horizontal plane. When Butler R. A. and Flannery R. (1980) disrupted normal binaural processing with a unilateral ear plug, the frequency content of a noise band altered the perceived laterality of the sound source. As illustrated in Figure 18, increasing the noise frequency from 4 to 8 kHz moved the apparent azimuth of the stimulus from opposite the unobstructed ear (negative 90°) to a frontal location (negative 15°). The pattern repeated at frequencies above 8 kHz, suggesting the existence of multiple spatial referent maps. Accurate localization was observed when the bandwidth of the stimulus was sufficient to overlap adjacent maps.

Implicit in studies of narrow band sound localization is a processing scheme that establishes sound source location by matching the proximal spectrum of the stimulus to the directional properties of outer ear acoustics. This relationship was directly tested by Middlebrooks J. C. (1992). Figure 19 plots the stimulus locations and ensuing responses of one subject for noise bands with a center frequency of 12 kHz. The columnar organization of the data in Figure 19(a) suggest that the azimuth of the sound source was localized with reasonable accuracy, presumably by attending to ILDs. Regardless of actual vertical and front–back coordinates, the subject most often identified a sound source near the horizontal plane (Figure 19(a)) and in the frontal field (Figure 19(b)). Two properties of these errors are noteworthy: they are systematic and they are confined to the dimensions of localization that are most closely linked to monaural spectral processing.

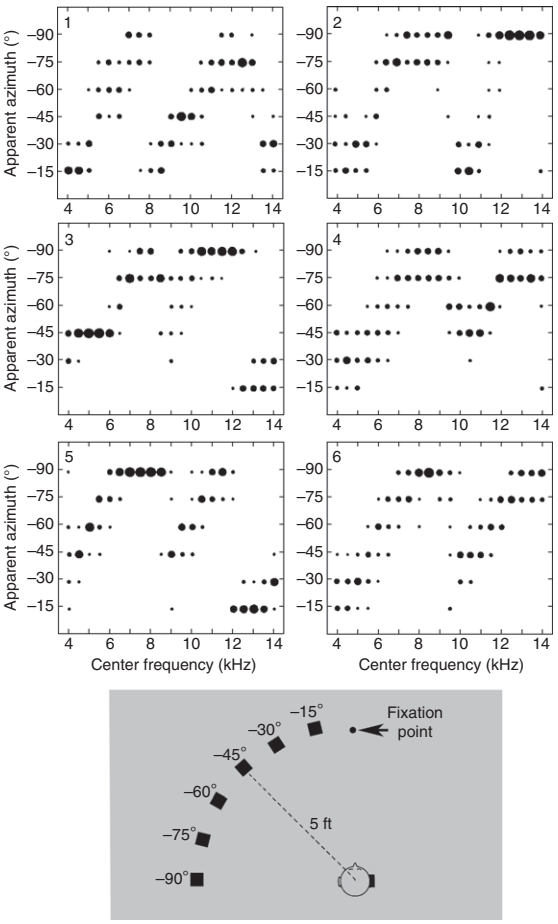

Figure 18 Apparent azimuth of 1 kHz wide noise bands with center frequencies of 4–14 kHz. Number of judgments is indicated by the size of the circle. Individual results are shown for six subjects. The arrangement of the speaker array is shown below. Adapted from Butler, R. A. and Flannery, R. 1980. The spatial attributes of stimulus frequency and their role in monaural localization of sound in the horizontal plane. Percept. Psychophys. 28, 449–457. with permission.

The spectral cues that potentially influence the localization behaviors of the listener are shown in Figure 19(c). These four DTFs have been selected because they correspond to response locations that occurred with the greatest frequency for 6, 8, 10, and 12 kHz noise bursts. Each function displays a tuned bandpass effect near the frequency that generated the matching spatial attribute. The filter shapes are reminiscent of the directional bands of Blauert J. and covert peaks of Musicant A. D. and Butler R. A.

Experiments with narrow bands of noise emphasize the importance of energy peaks in monaural localization. Other psychoacoustic procedures have focused on the directional properties of spectral notches. Hebrank, J. and Wright D., (1974) evaluated localization in the median plane using a number of high-pass, low-pass, band-pass, and band-stop filter conditions. Accurate localization required a sound spectrum with frequencies between 4 and 16 kHz. The noise band imparted a frontal directionality if it contained a spectral notch at frequencies between 4 and 10 kHz and increased energy at frequencies above 13 kHz. Increases in the lower cutoff of the notch raised the apparent elevation of the sound source.

A similar notch–frequency relationship was found by Butler R. A. and Belendiuk K. (1977). These investigators recorded the ear canal responses for noise sources in the median plane. Subjects could localize closed-field presentations of the recordings almost as well as their free-field counterparts. A spectral analysis of the recordings revealed a deep notch at frequencies between 5 and 9 kHz. The frequency of the notch changed with sound source elevation. The DTF in Figure 5(c) shows the notch for an elevation of 0°.

Bloom P. J. (1977) extended the findings of Butler R. A. and Belendiuk K. using a novel psychophysical approach. He assumed that tone detection thresholds would manifest pinna filtering effects if they were obtained under monaural conditions and if head movements were eliminated. After measuring thresholds at frequencies between 4 and 16 kHz using sound sources in the median plane, he derived the psychoacoustic eqivalent of DTFs by subtracting the average sensitivity curve from curves at individual locations. As previously noted in other psychoacoustic studies (Hebrank, J. and Wright, D. 1974; Butler, R. A. and Belendiuk, K. 1977), this behavioral method revealed a spectral notch that changed systematically in frequency with sound source elevation.

Bloom hypothesized that the spatial attributes of sounds in the median plane could be modified by adding spectral notches to the source spectrum. Subjects first listened to an unmodified reference stimulus from target elevations that ranged from ±45° and then created a matching vertical percept by adjusting the synthetic notch of a comparison stimulus from an eccentric location with a relatively featureless transfer function. He noted a strong correlation between natural occurring notches and the synthetic notches of illusionary source locations.

The subjects of animal behavioral studies are also sensitive to perturbations of the natural spectral cues that govern vertical sound localization. Cats make

accurate head orientation responses to brief bursts of broadband noise (May, B. J. and Huang, A. Y., 1996). If the noise spectrum is truncated in a manner that preserves mid-frequency spectral notches (Figure 10), performance is spared (Huang, A. Y. and May, B. J., 1996a). Broadband sounds lacking notch frequencies and pure tones elicit large elevation errors. These deficits are not observed in spatial acuity tasks that do not require absolute localization of the sound source (Huang, A. Y. and May, B. J., 1996b).

An unexpectedly robust demonstration of the directionality of spectral notches was observed in the context of summing localization by Tollin D. J. and Yin T. C. (2003). Like humans, cats may confuse two sound sources as a single spatial image. The fused location is determined by the relative timing of stimulus onsets. Short interstimulus delays sum to create the illusion of an intermediate location that is biased toward the leading speaker. When Tollin, D. J. and Yin, T. C. applied this principle, they noticed that sound sources in the horizontal plane evoked orientation responses that were also shifted toward higher elevations.

An explanation for the ventriloquial quality of the summed stimulus is presented in Figure 20. As previously noted by May B. J. and Huang A. Y. (1996) , systematic changes in notch frequency are correlated with accurate orientation responses to single sound sources in the median plane (Figure 20(a)). Notch frequencies of 12–13 kHz are associated with elevations of 9–18°. When broadband energy from symmetrical locations in the horizontal plane is summed, binaural difference cues are minimized and monaural spectral cues mimic the HRTF of an elevated source (Figure 20(b)).

C. 2003. Spectral cues explain illusory elevation effects with stereo sounds in cats. J. Neurophysiol. 90, 525–530. Copyright (2003), used with permission from The American Physiological Society.

The spectral manipulations that alter the spatial hearing of humans and animals suggest that members of the same species rely on a common set of localization cues. A principal component analysis by Kistler D. J. and Wightman F. L. (1992) has confirmed that 90% of the individual variance of human HRTFs can be explained by the linear summation of five basis functions. Middlebrooks J. C. and Green D. M. (1992) reached the same conclusion using different analysis techniques. Similarities between the independently derived basis functions are remarkable.

Although the gross acoustic properties of the external ear are conserved across individuals, best immediate virtual localization is achieved when sounds are shaped by the listener's own HRTFs (Butler, R. A. and Belendiuk, K., 1977; Morimoto, M. and Ando, Y., 1982; Wenzel, E. M. *et al.*, 1993). Nonindividualized transfer functions evoke poor elevation accuracy and front–back confusion. The binaural processes that support horizontal localization are more robust, presumably because their directional properties are less individualized (Wightman, F. L. and Kistler, D. J., 1998).

Intersubject differences in localization cues are highly correlated with the physical dimensions of the listener (i.e., interaural delays, size of the external ear, and head width) (Middlebrooks, J. C., 1999a; Xu, L. and Middlebrooks, J. C., 2000). Acoustic measurements have shown that the disparities are reduced by compressing or expanding the frequency axis of DTFs. This relationship suggests that virtual sound localization may be enhanced by scaling procedures that align synthetic spectral shapes with the listener's natural cues. These findings have important implications for the design of generic sound fields with realistic directional qualities.

Frequency scaling has been used successfully to improve performance in virtual localization tasks (Middlebrooks, J. C., 1999b). The resulting benefits are particularly evident when elevation judgments are based on other-ear transfer functions. The magnitude of response errors is halved in most listeners.

A limitation for the practical application of frequency scaling is that detailed acoustic measurements are needed to optimize the match between synthetic and natural localization cues. In the absence of these measures, the most veridical scale factor must be estimated from an individual's physical dimensions or by confirming its reliability with psychophysical procedures (Middlebrooks, J. C. *et al.*, 2000).

The spatial illusions created by spectral peaks and notches imply that the auditory system is making assumptions regarding the transformation of the source spectrum by the directional filtering properties of the outer ear. The dilemma is: how does the auditory system distinguish a spectral feature that is introduced by the ear from a feature that exists at the sound source? It remains a matter of debate whether this information is available for familiar sounds or must be recovered by the auditory system.

Rakerd B. *et al.* (1999) addressed the question of stimulus familiarity by training listeners to identify band–band noise tokens with different spectral peaks and notches. After a brief training period, identification errors were uncommon when the stimuli were presented from a fixed location in the median plane but increased when the source location changed randomly across presentations. The magnitude of the deficit in the roving speaker condition was related to the center frequency of the noise. Frequencies less

than 3 kHz yielded near normal identification rates, while frequencies above 8 kHz approached chance performance. This dependency suggests that listeners could not dissociate the source spectrum from pinna-based features that are introduced at frequencies above 3 kHz. Knowledge of the sound's location did not influence these results. Listeners did not show better identification for spectral shapes that were accurately localized.

In contrast to the narrow bands of noise or spectral notches that evoke spatial illusions, most naturally occurring sounds have locally constant slopes (Zakarauskas, P. and Cynader, M., 1993). Consequently, very sharp pinna-filtering effects create spectral discontinuities that can support accurate monaural localization. In addition, each ear exerts a unique filtering effect when sounds outside the median plane contact the head with different incident angles. Subtle disparities in the transfer functions of the two pinnae yield similar differences when sounds occur within the median plane (Searle, C. L. *et al.*, 1975). Binaural spectral comparisons may allow the listener to isolate these local filtering effects. Regardless of the mechanism, the auditory system resolves these ambiguities under all but the most extreme stimulus conditions. Such spatial illusions are rare for natural sounds.

3.37.8 Lesions of the Spectral Processing Pathway

Lesions of the spectral processing pathway reveal the contributions of the ear and brain to sound localization behavior. Critical central auditory nuclei can be silenced by design in experimental animals with controlled surgical lesions. No less profound are the unplanned processing deficits that afflict humans when the cochlea is damaged by disease, acoustic overexposure, or aging.

3.37.8.1 Cochlear Deficits

A complete loss of auditory function in one ear does not preclude accurate sound localization if normal hearing is maintained in the opposite ear (Slattery, W. H., 3rd and Middlebrooks, J. C., 1994). A more common form of peripheral deafness is the progressive bilateral loss of high-frequency hearing that affects virtually all adult humans. This condition is known as presbycusis (Gates, G. A. and Mills, J. H., 2005). Assessments of directional hearing in presbycusis patients suggest that sound localization is resistant to high-frequency hearing loss (Colburn, H. S., 1982; Rosenhall, U., 1985). Existing audiological measures have focused on sound localization in the horizontal plane. Under these conditions, sound source laterality may be derived from ITD cues, if low frequencies are present and the listener possesses residual low-frequency hearing (Wightman, F. L. and Kistler, D. J., 1992).

Rakert B. *et al.* (1998) extended the psychophysical assessments of presbycusis patients to locations that were more closely linked to high-frequency spectral processing. These subjects showed normal localization in the horizontal plane but rarely scored above chance for sources in the median or sagittal planes. Hearing aid amplification of the high-frequency spectral cues significantly improved performance.

The deficits in spatial processing that accompany hearing loss are not exclusively directional. A listener's ability to segregate simultaneous streams of competing sounds or separate auditory signals from background noise is intricately bound to localization processes (Cherry, E. C., 1953; Hirsh, I. J., 1950). For these reasons, presbycusis often leads to perceptual abnormalities in masking, speech intelligibility, and loudness recruitment before overt hearing loss. As the far ranging consequences of spatial hearing are recognized, strategies for deafness rehabilitation are placing greater emphasis on the preservation of binaural hearing and pinna acoustics (Lin, L. M. *et al.*, 2006).

Outer hair cells are a primary site for the early stages of cochlear deafness (Rokay, E. and Penzes, L., 1988; Soucek, S. *et al.*, 1987). These sensory neurons are innervated by descending olivocochlear efferent fibers (Kimura, R. and Wersall, J., 1962). The cholinergic effects of the olivocochlear projections modulate cochlear sensitivity and frequency tuning by altering the voltage-sensitive electromotile properties of outer hair cells (Fuchs, P., 2002). Electrical stimulation of the olivocochlear bundle can expand the dynamic range properties of auditory-nerve fibers, particularly when transient signals are embedded in continuous background noise (Guinan, J. J., Jr. and Gifford, M. L., 1988; Wiederhold, M. L., 1970; Winslow, R. L. and Sachs, M. B., 1987).

An intriguing aspect of olivocochlear anatomy is the prolific innervation of the middle turns of the cat's cochlea (Liberman, M. C. *et al.*, 1990). This projection pattern augments efferent feedback at frequencies between 5 and 20 kHz (Wiederhold, M. L., 1970), and therefore may enhance the coding of

mid-frequency spectral notches that are critical for accurate localization behaviors (Huang, A. Y. and May, B. J., 1996a). May B. J. *et al.* (2004) investigated the role of efferent feedback in sound localization by lesioning the olivocochlear bundle of domestic cats. The specificity of the resulting deficits was striking. Lesioned cats maintained normal directional hearing when sound sources changed location in the horizontal plane. Spatial acuity decreased moderately in the median plane under quiet conditions and was severely disrupted in the presence of background noise. With sufficient training, a number of cats recovered normal function. These findings suggest that the peripheral representation of spectral cues was altered but not eliminated by the disruption of efferent feedback.

3.37.8.2 Experimental Lesions of the Dorsal Cochlear Nucleus

The behavioral significance of spectral processing in the DCN has been explored by evaluating the auditory deficits of cats with surgical lesions of the dorsal acoustic stria (May, B. J., 2000). These fibers are the ascending axons of the type-IV principal cells that link the DCN to ICC. In previous studies, the surgical procedure did not change hearing sensitivity or the detection of signals in noise (Masterton, R. B. and Granger, E. M., 1988; Masterton, R. B. *et al.*, 1994). It did diminish the accuracy of reflexive head orientations to bursts of noise in the median plane (Sutherland, D. P. *et al.*, 1998b). The surgical procedure had no effect on the discrimination of sound source elevation (Sutherland, D. P. *et al.*, 1998a), leading Sutherland and Masterton to hypothesize that the loss of function involved the formulation of the orientation response. One explanation for the specificity of the deficit is that absolute localization competency is required to make accurate head orientations but not to discriminate spatial differences.

The orientation plots in Figure 21(a) illustrate the head pointing behaviors of one cat before lesions of the dorsal acoustic stria (May, B. J., 2000). These tests were conducted with band-pass noise to restrict the domain of HRTF-based spectral information to the mid-frequency notches that exist at 5–20 kHz. As predicted by the results of previous spectral manipulations (Huang, A. Y. and May, B. J., 1996a), the cat exhibited well-directed orientation responses prior to the lesion. The cat slightly underestimated locations when the noise bursts were presented from high elevations. Mid-frequency spectral notches are not a

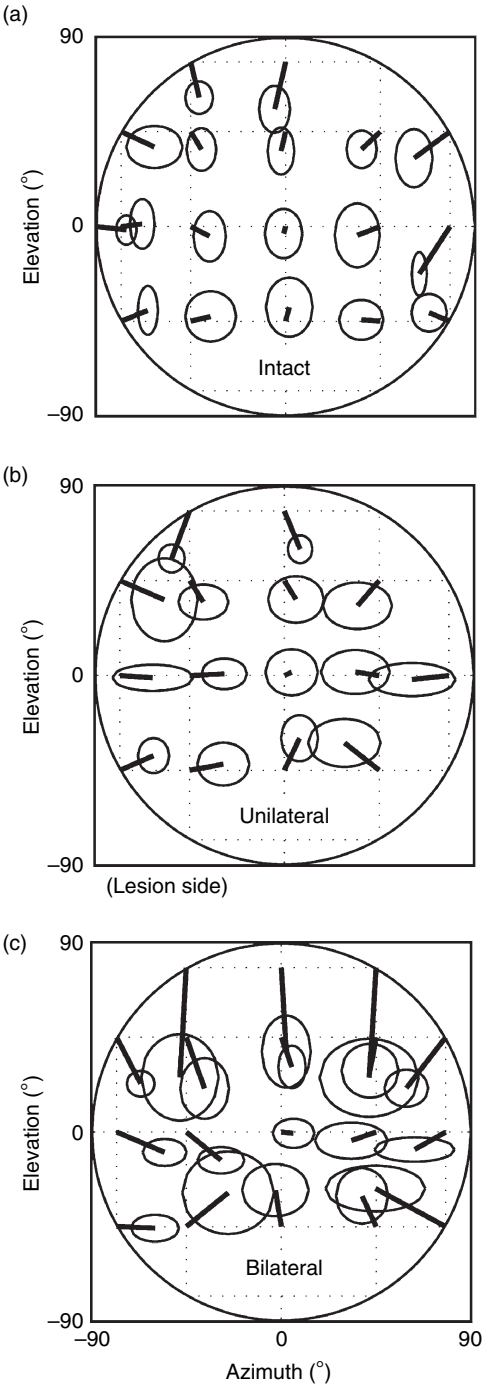

Figure 21 Effects of strial lesions on sound-evoked orientation behavior. Results are shown for one cat before the lesions (a), and after unilateral (b) and bilateral lesions of the dorsal acoustic striae (c). Each ellipse represents the SD of azimuth and elevation for orientation responses to the speaker location indicated by the adjoining line segment. Reproduced from May, B. J. 2000. Role of the dorsal cochlear nucleus in the sound localization behavior of cats. Hear. Res. 148, 74-87. Copyright (2000), with permission from Elsevier.

prominent feature of the HRTF at these eccentric angles of incidence (Rice, J. J. *et al.*, 1992).

Orientation behaviors were only slightly degraded if the dorsal acoustic stria was left intact on one side of the brain (Figure 21(b)). The cat distinguished the elevation and azimuth of most test locations, although the variability of responses increased slightly. Errors at eccentric locations grew in magnitude but remained localized to those spatial regions that proved most difficult to intact subjects. These results suggest that monaural spectral cues can support relatively accurate localization over a wide range of source locations. Similar response patterns have been noted in psychophysical studies of monaural humans (Angell, J. R. and Fite, W., 1901b; Slattery, W. H., 3rd and Middlebrooks, J. C., 1994).

Large localization errors were noted after a second lesion disrupted spectral processing pathways on both sides of the brain (Figure 21(c)). These localization deficits were statistically significant only in terms of response elevation. Regardless of the actual location of the sound source, the subject's orientation responses were seldom directed toward elevations that deviated more than 20° from the interaural horizontal plane. The systematic underestimations could exceed 60° for extreme source locations.

It is likely that cats with bilateral DCN lesions maintained accurate lateral localization by relying on the ILD and ITD cues that are processed in the intact binaural pathways (Batteau, D. W., 1967; Musicant, A. D. and Butler, R. A., 1984a). This interpretation was investigated by acutely disrupting binaural processing in lesioned cats with unilateral ear plugs. The manipulation is predicted to have less impact on intact cats that can learn to rely on monaural spectral cues (Hofman, P. M. *et al.*, 1998; Van Wanrooij, M. M. and Van Opstal, A. J., 2005).

The effects of a unilateral ear plug before and after DCN lesions are contrasted in Figure 22. Orientation responses of an intact cat conform well to target localizations except at extreme lateral positions opposite the plugged ear (Figure 22(a)). These results were collected after the cat had habituated to the plug. Acute ear plug effects were more severe, as has been noted in humans (Slattery, W. H., 3rd and Middlebrooks, J. C., 1994).

When monaural spectral processing was surgically eliminated and binaural inputs acoustically altered (Figure 22(b)), the lesioned cat made robust errors at all target locations. A direct comparison of the orientation behaviors of the lesioned cat with normal binaural processing (Figure 21(c)) and the lesioned

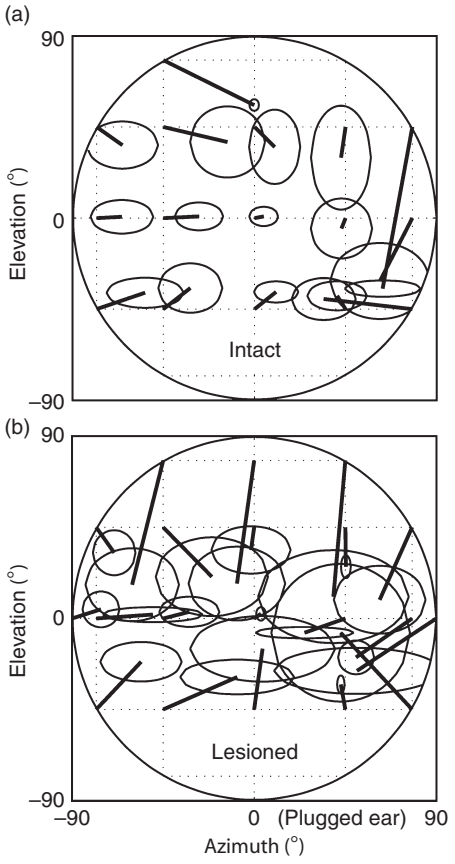

Figure 22 Effects of an acute ear plug (right ear) on orientation behavior. Responses of one cat are compared before (a) and after bilateral lesions of the dorsal acoustic striae (b). Plotting conventions are described in Figure 21. Reproduced from May, B. J. 2000. Role of the dorsal cochlear nucleus in the sound localization behavior of cats. Hear. Res. 148, 74–87. cat with an ear plug (Figure 22(b)) suggests that horizontal accuracy is the critical difference in their localization abilities.

Spatial discrimination procedures have been conducted in cats with bilateral DCN lesions to verify the specificity of deficits first reported by Sutherland and Masterton (May, B. J., 2000). These experiments are summarized by the psychometric functions in Figure 23. Each function represents the postlesion performance of one cat for directional changes in the horizontal (Figure 23(a)) and median planes (Figure 23(b)). The test stimuli were mid-frequency noise bursts.

All of the cats exhibited orientation deficits. None of the subjects showed signs of impaired spatial

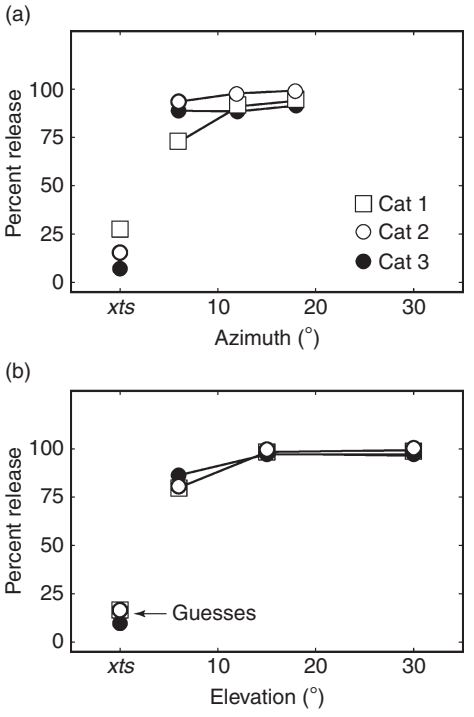

Figure 23 Effects of strial lesions on the discrimination of sound sources in the horizontal (a) and median planes (b). Results are shown for one cat after bilateral lesions of the dorsal acoustic striae. Psychometric functions plot the percentage of correct responses in relation to the magnitude of changes in location. False-positive responses (guesses) are estimated by catch trials that did not include changes in location (xts). Reprinted from May, B. J. 2000. Role of the dorsal cochlear nucleus in the sound localization behavior of cats. Hear. Res. 148, 74–87. Copyright (2000), with permission from Elsevier.

discrimination. These results confirm that DCN lesions do not lead to generalized hearing deficits and further support the notion that spatial acuity and directional identification are based on different auditory cues and processing pathways.

A loss of cochlear inputs to the DCN has been associated with the perception of phantom sound, or tinnitus (Moller, A. R., 2003). Although the etiologies and physiological consequences of this pervasive hearing disorder are varied, elevated activity in the absence of sound stimulation is a common outcome when animal models are subjected to experimental manipulations that are known to induce tinnitus in humans.

Tinnitus-related hyperactivity has been observed in the DCN (Brozoski, T. J. and Bauer, C. A., 2005; Imig, T. J. and Durham, D., 2005; Kaltenbach, J. A. *et al.*, 2005) and ICC (Chen, G. D. and Jastreboff, P. J., 1995; Jastreboff, P. J. and Sasaki, C. T., 1986; Ma, W. L. *et al.*, 2006). A unifying property of these structures is that their normal sound-driven responses are sculpted by both auditory and nonauditory inputs. For example, the granule cell layer of the DCN receives somatosensory and vestibular inputs that are thought to integrate the auditory processing of sound localization cues with head and pinna movements (Davis, K. A. *et al.*, 1996; Kanold, P. O. and Young, E. D., 2001). Interestingly, many patients can modify the strength of their tinnitus percepts by maneuvers of the jaw, head, and neck (Levine, R. A. *et al.*, 2003). Tinnitus may arise when these somatosensory–auditory interactions are no longer regulated by the intrinsic inhibitory circuitry of the DCN (Ma, W. L. and Young, E. D., 2006). This is an area of intense physiological research.

3.37.8.3 Experimental Lesions of the Inferior Colliculus and Its Projections

The neuroanatomical basis of sound localization has also been investigated by evaluating the effects of surgical lesions beyond the cochlear nucleus (Aitkin, L. M., 1986). None of these paradigms have looked exclusively at monaural spectral processing but they are nevertheless relevant because they often involve bilateral lesions that are completed in a two-stage process. Functional assessments that precede the second surgical procedure offer insights into monaural performance.

A consensus among lesioning studies is that damage to the lower commissural pathways exerts a pervasive effect on sound localization (Casseday, J. H. and Neff, W. D., 1975; Jenkins, W. M. and Masterton, R. B., 1982; Masterton, R. B. *et al.*, 1967; Moore, C. N. *et al.*, 1974). Masterton and colleagues demonstrated these deficits with shock-avoidance procedures. Cats were conditioned to avoid the shock by jumping a barrier to the safe side of a double grill box. A warning sound indicated the shock was about to be delivered. The procedure was adapted to sound localization by training the cats to wear a helmet that was equipped with binaural hearing aids. The closed-field sound system allowed the investigators to precisely control the directional properties of the auditory stimuli. Pinna-based localization cues and ILDs were eliminated, but ITD cues gave the stimuli a spatial lateralization within the head (Plenge, G., 1974).

The complexity of the stimulus conditions that warned of the impending shock were manipulated to

determine the specificity of lateralization deficits. In two tasks, the warning stimulus was a train of clicks in the right ear and the safe stimulus was either silence (discrimination #1) or a train of clicks in the left ear (discrimination #2). These tests did not assess binaural hearing. They were used as a procedural control to ensure that lesioned subjects maintained the ability to hear auditory stimuli.

Discrimination #3 was more directly linked to binaural processing. A right to left pattern of click pairs (RL) signaled the warning state and a left to right pattern (LR) indicated the safe condition. The binaural click pairs were separated by 50 μs. For cats with normal ITD processing, this short interaural delay creates a fused lateralized percept making the task equivalent to R versus L discrimination (discrimination #2). Lesions that impair ITD processing produce a specific loss of discrimination #3. The magnitude of the deficit was quantified by varying the time delay between clicks (Δt).

Cats with a complete unilateral lesion of the trapezoid body continued to perform the L versus R tasks but exhibited a severe disruption of LR versus RL binaural discrimination (Masterton, R. B. *et al.*, 1967). The deficit was related to a large shift in Δt sensitivity. Although normal cats discriminated time delays of less than 50 μs, lesioned cats required delays greater than 500 μs. Time disparities of this magnitude cannot be realized under natural free-field conditions (Roth, G. L. *et al.*, 1980).

Complete unilateral lesions of the trapezoid body also involved the dorsal and intermediate acoustic striae and the superior olive. Given this extensive damage, it is not clear how the central auditory pathways retained any capacity for binaural processing. Observations in cats with partial lesions of the trapezoid body or lateral lemniscus suggest that ITD processing is robust to surgical manipulation (Masterton, R. B. *et al.*, 1967). Near normal LR versus RL discrimination was possible if surgical procedures spared only a fraction of the projections in either pathway. It is likely that broadband clicks enhanced the usefulness of any surviving fibers by conveying Δt cues across the widest possible frequency range.

The effects of ICC lesions also may be dissociated by comparing the functional consequences of complete versus partial lesions (Masterton, R. B. *et al.*, 1968). A deep bilateral lesion of the nucleus, or its ascending pathways (brachium), impaired not only LR versus RL discrimination but also the discrimination of L versus R clicks. In the latter case, monaural discrimination could be improved by additional ILD cues. Superficial lesions that were restricted to the apical ICC did not disrupt lateralization behaviors. Consequently, ITD discrimination was possible if binaural information could enter the basal nucleus via the lateral lemniscus and then ascend to the forebrain via the brachium.

Masterton and his colleagues isolated ITD processing deficits by forcing subjects to attend to a single directional cue under closed-field conditions. Although these lateralization paradigms provide classic examples of functional organization, they do not predict how sounds are localized under circumstances that afford the full complement of ITD, ILD, and spectral cues. For example, cats with unilateral cochlear ablations fail to lateralize LR versus RL stimuli because they lack the requisite binaural processes (Masterton, R. B. *et al.*, 1967), but unilaterally deaf humans show surprisingly good directional hearing because they have learnt to replace compromised binaural processes with monaural spectral information (Angell, J. R. and Fite, W., 1901b; Slattery, W. H., 3rd and Middlebrooks, J. C., 1994). The localization deficits of lesioned cats change dramatically when performance is measured in free field.

Neff and colleagues revisited the effects of central auditory lesions on sound localization in cats (for a complete contemporary review, see Neff, W. D. *et al.*, 1975). Their lesioning procedures were similar to those used in earlier studies by the Masterton group, but behavioral deficits were characterized in a free-field testing arena (Figure 24). In their two-alternative forced-choice paradigm, an active speaker signaled the availability of a food reward that could be taken from a proximal receptacle. The goal box on the alternative speaker could not be opened. Directional thresholds were determined by changing the physical separation between speakers.

An advantage of the goal-box paradigm is that it is a true localization task that requires the subject to identify and approach a sound source (the testing environment is darkened to minimize visual cues). A disadvantage, at least for the analysis of spectral processing pathways, is that the speaker/goal box combinations are arranged along the floor of the testing arena and therefore measure localization only in the horizontal plane.

Moore C. N. *et al.* (1974) used the goal-box paradigm to investigate the effects of commissural lesions on sound localization. As a baseline measure, one cochlea was destroyed in two cats. The lesion elevated average prelesion directional thresholds of less than 5° to postlesion thresholds of over 15°. The

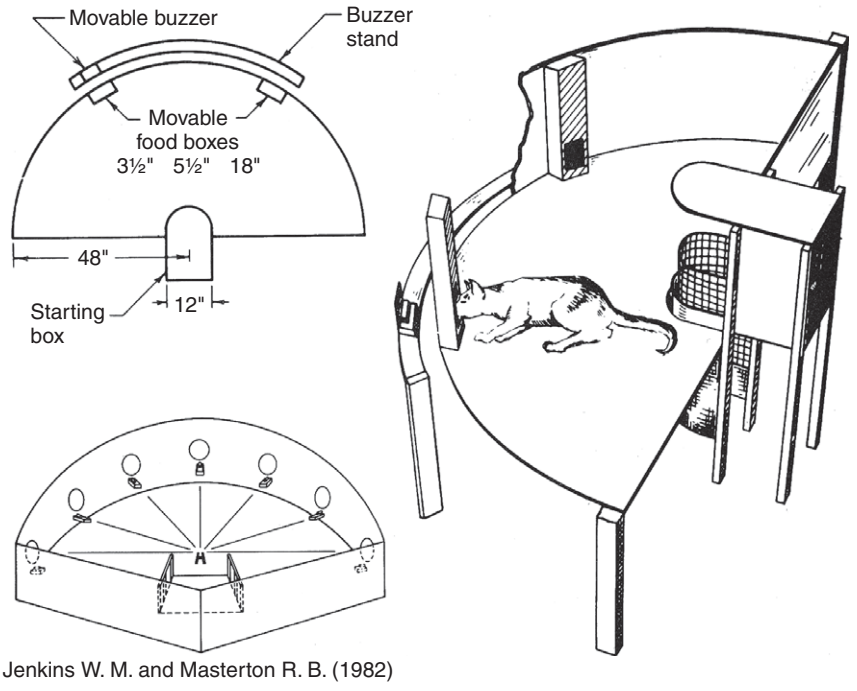

Figure 24 Goal-box apparatus for measuring horizontal localization. The subject is released from the starting box and approaches the active sound source to obtain a food reward. Initial experiments were conducted with two speaker choices. Jenkins W. M. and Masterton R. B. (1982) increased the speaker number to seven. Adapted from Irvine, D. R. F. 1986. The Auditory Brainstem, Springer. Copyright (1986), with kind permission of Springer Science and Business Media.

subjects' performance was not greater than chance during initial postoperative sessions but showed a gradual improvement with extensive retraining. The auditory stimulus for these experiments was a broadband buzzer making it likely that the recovery of function reflects an increased attention to monaural spectral cues.

The remaining seven cats were subjected to lesions of the trapezoid body, commissure of the ICC, and corpus callosum. Although the extent of the lesions varied between subjects and multiple lesions were performed on some cats, the results suggest a striking lack of effect for lesions at higher processing levels. Destruction of the commissures of the ICC or cerebral cortex changed average prelesion thresholds by less than 0.5°. The cats did not require postoperative retraining.

Lesions of the trapezoid body produced more variable results. At the extreme, one cat (459) showed a complete loss of directional acuity that gradually recovered to a 25° threshold increase over more than 500 training trials. Another cat (559) was virtually unaffected by the lesion. In part, these differences may be explained by the extent of damage. The lesion in cat 459 effectively isolated the left cochlear nucleus by destroying all ascending fibers (dorsal and intermediate acoustic striae and lateral lemniscus) as well as crossing fibers in the trapezoid body. The lesion in cat 559 destroyed the left superior olive and transected the trapezoid body, but spared the dorsal and intermediate acoustic striae.

From the perspective of sound localization pathways, the lesion of cat 459 must compromise not only the binaural interactions that are established by the crossing projections of the ventral cochlear nuclei but also the monaural ascending projections of the DCN. By contrast, the lesion of cat 559 suggests extensive damage to the binaural system but less involvement of the spectral processing pathway. Given recent functional measures (May, B. J., 2000), it is possible that binaural deficits in cat 559 were masked by the availability of spectral cues in both ears.

Like Masterton and his colleagues, Casseday J. H. and Neff W. D. (1975) lesioned the trapezoid body, lateral lemniscus, and brachium of the ICC. Consequential localization deficits were only noted for trapezoid body lesions, and as noted in their previous study (Moore, C. N. *et al.*, 1974), these

effects were complete and permanent in only a subset of subjects. An interesting distinction between these and previous trapezoid body lesions is that they were performed near the midline of the brainstem and therefore did not directly involve the cochlear nuclei. Here, the magnitude of the impairment was related to the depth of the lesion. Cats with the deepest lesions made localization errors that exceeded those observed after unilateral cochlear ablation. Histological results suggest that the deep medullary incisions included a bilateral transection of the intermediate and dorsal acoustic striae as they crossed the brainstem en route to the ICC. Presumably, one spectral pathway is spared by unilateral cochlear ablation. These results provide further evidence that severe localization impairments require the combined disabling of binaural and spectral processing.

Subsequent results by Jenkins W. M. and Masterton R. B. (1982) raise important questions regarding the use of the goal-box paradigm. The issue is not the task itself, but the potential to apply other decision criteria to the two-alternative forced choice. For example, when two sound sources are located to the left and right of the listener, a normal subject may perform the task by discriminating left versus right. On the other hand, a subject with a rightward directional impairment may maximize correct responses by discriminating left versus not-left, or even loud versus quiet if there is an accompanying hearing loss. These ambiguities were corrected by increasing the number of sound sources in the semi-circular arena. With the seven speaker array, the cat was required to select the active speaker from multiple locations in the left or right hemifield (Figure 24). The correct choice offered brief access to a water reward.

The effects of trapezoid body lesions on performance in the more complex localization task were similar to those previously noted with the two-choice paradigm (Casseday, J. H. and Neff, W. D., 1975; Moore, C. N. *et al.*, 1974). Results for lesions of higher auditory structures were quite different. Unlike the transient effects observed by Casseday and Neff, unilateral damage of the lateral lemniscus, ICC and brachium yielded profound and permanent impairments. In most instances, the deficits were confined to locations that were contralateral to the lesion site.

Representative lesioning results are summarized in Figure 25. This cat (case 907) received a complete lesion of the left lateral lemniscus (Figure 25(a)). When tested with the multispeaker array, the cat showed a high percentage of correct localization responses for speakers in the ipsilateral (left) field (Figure 25(b)). Correct responses declined precipitously as source locations moved toward contralateral (right) azimuths. The cat rarely responded to locations in the contralateral field.

A more detailed description of the pattern of localization errors is provided in Figure 25(c). The stimulus–response matrix plots the azimuth of the speaker on the horizontal axis and the azimuth of the response on the vertical axis. Numerical values indicate the number of incorrect responses for each speaker–response combination out of 30 postoperative trials. For example, the 90° speaker in the ipsilateral field produced only eight errors out of 30 trials, while the 90° speaker in the contralateral field was never correctly localized. Most incorrect responses in the ipsilateral field occurred when the subject responded to the adjacent speaker. Errors in the contralateral field spanned the entire 180° speaker range.

To explain the discrepancies between these responses and previous results with the two-speaker paradigm, Jenkins W. M. and Masterton R. B. (1982) conducted additional tests using single speakers at left and right azimuths of 30°. Responses of cat 907 in the simplified testing environment are indicated by the star symbols in Figure 25(b). As noted by Casseday J. H. and Neff W. D. (1975), the subject was able to attain near-perfect discrimination of left versus right locations.

Results with the seven-speaker array led Masterton and his colleagues to propose the existence of an acoustic chiasm (Glendenning, K. K. and Masterton, R. B., 1983; Masterton, R. B., 1997), that creates a contralateral representation of auditory space at processing levels above the decussation of the trapezoid body. Physiological support for this interpretation can be seen in the contralateral preference of spatial tuning in the ICC (Figure 15). A significant proportion of these directional effects are observed under monaural conditions (Delgutte, B. *et al.*, 1999).

3.37.9 Species Comparisons of the Spectral Processing Pathway

Ablation paradigms evaluate the functional importance of neuroanatomical structures by comparing the behavioral performance of subjects with normal and surgically altered systems. A persistent problem

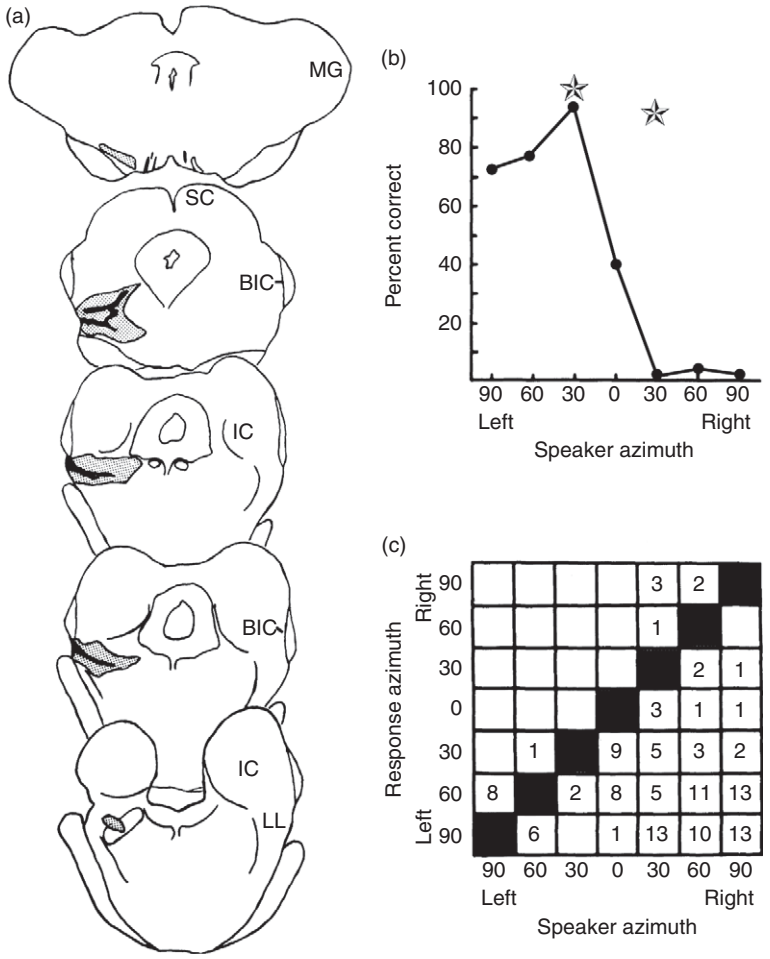

Figure 25 Effects of a unilateral inferior colliculus lesion on sound localization. (a) Histological reconstruction of the unilateral lateral lemniscus lesion in case 907. (b) Psychometric function plotting the percentage of correct localization responses in relation to the azimuth of seven speakers. Results obtained with two speakers are indicated by star symbols. (c) Stimulus–response matrix for the localization errors of case 907. Each column of numbers indicates the total errors out of 30 trials for the speaker location indicated on the horizontal axis. The spatial distribution of the errors is indicated on the vertical axis. Abbreviations: BIC, brachium of the inferior colliculus; IC, inferior colliculus; LL, lateral lemniscus; MG, medial geniculate nucleus; SC, superior colliculus. Reproduced from Jenkins, W. M. and Masterton, R. B. 1982. Sound localization: effects of unilateral lesions in central auditory system. J. Neurophysiol. 47, 987–1016. Copyright (1982), used with permission from The American Physiological Society.

with the lesioning approach is its inherent variability. When the lesion is too small, destruction is incomplete. When the lesion is too large or misplaced, surrounding structures are compromised. Either outcome leads to ambiguous structure/function relationships. Masterton followed his lesioning studies of the auditory brainstem with a novel alternative to surgical ablations (Masterton, B. *et al.*, 1975). These natural ablation studies compared the sound localization behaviors of domestic cats to a menagerie of unusual mammalian species representing the evolutionary development of the medial superior olive (MSO). As shown in Figure 26(a), hedgehogs have no MSO. Rats, tree shrews, and cats form a continuum of increasing MSO size and cell number (additional species are described in Heffner, R. S. and Masterton, R. B., 1990). Thus, naturally occurring variations in the anatomy of the ITD pathway could be systematically related to directional acuity without surgical intervention.

Sound localization accuracy was measured with the two-speaker paradigm that was developed by the Neff group (Figure 24). The left/right speaker separation was 60°, which is an easily detectable

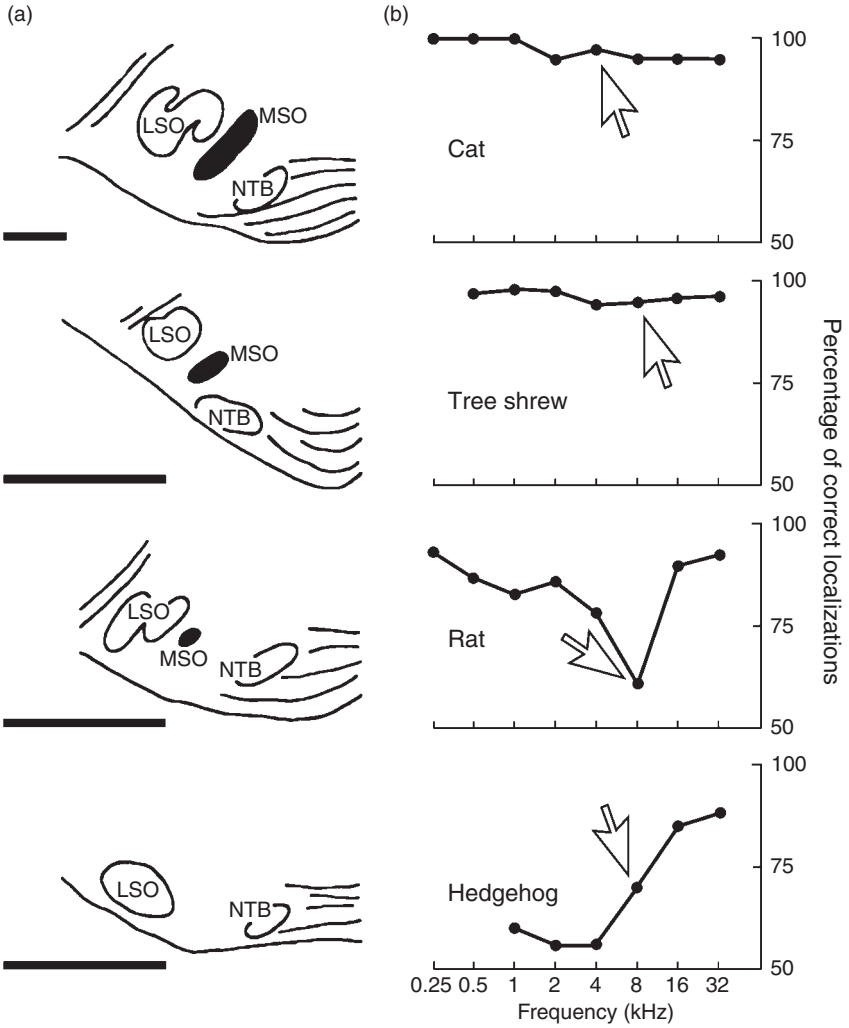

Figure 26 Comparative analysis of ITD processing. (a) Brainstem anatomy showing species variations of the medial superior olive (black fill). The structure is missing in the hedgehog. (b) Effects of frequency on the correct localization of a 60° speaker change. Arrows indicate the low-frequency cutoff of ILD cues based on the physical dimensions of the subject's head. Hedgehogs failed to localize pure tones below 16 kHz and were not tested at the lowest frequencies. Abbreviations: LSO, lateral superior olive; MSO, medial superior olive; NTB, nucleus of the trapezoid body. Scale bar indicates 1 mm. Reprinted from Masterton, R. B., Thompson, G. C., Bechtold, J. K., and RoBards, M. J. 1975. Neuroanatomical basis of binaural phase-difference analysis for sound localization: a comparative study. J. Comp. Physiol. Psychol. 89, 379–386 (1975) ©, with permission from American Physiological Association.

change in source location for most mammalian species (Fay, R. R., 1988). Instead of the usual noise burst, the auditory stimulus was a tone pip that ranged in frequency from 250 to 32 kHz. This important modification of the testing procedure allowed the investigators to compare each species' performance at low versus high frequencies. Accurate responses across the entire frequency range reflect the subject's ability to make use of both ITD and ILD cues (Casseday, J. H. and Neff, W. D., 1973; Mills, A. W., 1958).

The effects of frequency varied across species (Figure 26(b)). All subjects showed near-perfect discrimination at high frequencies where the physical dimensions of the head are expected to create large ILD effects. These binaural cues were presumably processed in the lateral superior olive. The three species with an anatomically distinct MSO also performed well at low frequencies, although the performance of the rat declined at intermediate frequencies where there is a transition between ILD and ITD cues. Humans show comparable deficits at lower

frequencies because of their larger head size (Stevens, S. S. and Newman, E. B., 1936). Of particular interest is the complete breakdown of the hedgehog's behavior at frequencies below 16 kHz. The frequency dependency of the deficit suggests an inability to process ITD information.

Application of the natural ablation method to the spectral processing pathway is problematic. All mammalian species possess a DCN and ICC. Nevertheless, the essence of the approach may be achieved by supplanting anatomical classifications with criteria that are based on unique physiological characteristics. It may even be argued that physiological dichotomies are more closely linked to species-specific perceptual behaviors.

Figure 27 contrasts the spectral integration properties of ICC neurons in the cat and mouse. Both species show the same types of frequency response maps (Figure 27(a)), but there are clear differences in the prevalence of the major unit types (Figure 27(b)).

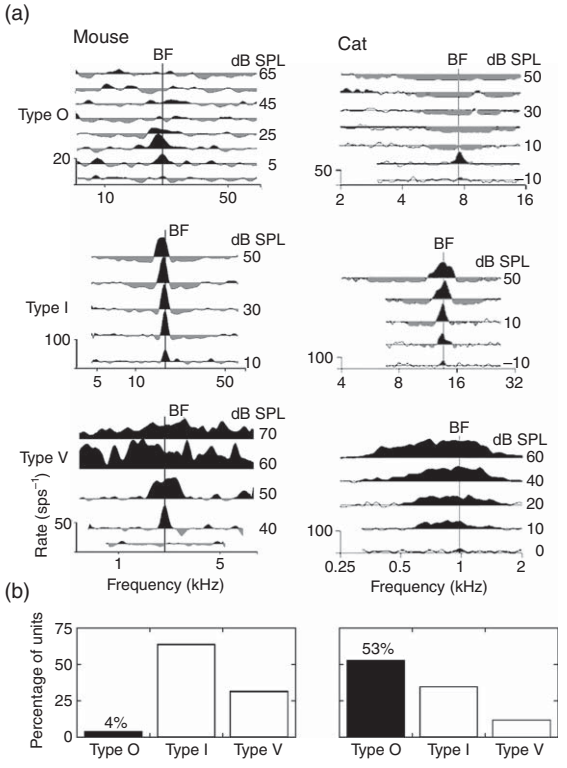

Figure 27 Comparative analysis of spectral processing. (a) Frequency response maps in the inferior colliculus of mice (left column) and cats (right column). Both species show the same physiological response types. (b) The distribution of response types. Type-O responses (black fill) are rare in mice but common in cats. Plotting conventions of frequency response maps are described in Figure 16.

Notch-selective type-O responses are common in cats (Ramachandran, R. *et al.*, 1999), but rarely encountered in mice (Egorova, M. *et al.*, 2001; Ehret, G. *et al.*, 2003; Ma, W. L. *et al.*, 2006). Additional physiological results from the mouse ICC (Vartanyan, I. A. and Malinina, E. S., 2004) confirm the more generalized notch frequency sensitivity of type-I units (Figure 16), and not the spatially selective responses of type-O units (Figure 17). A similar under-representation of spectral processing specializations has been observed in guinea pigs (LeBeau, F. E. *et al.*, 2001), rats (Malmierca, M. S. *et al.*, 2003), and gerbils (Gdowski, G. T. and Voigt, H. F., 1997).

The lack of a dedicated spectral processing pathway in the prey species predicts poor monaural sound localization. As previously noted, well-established physiological and psychophysical procedures are capable of validating this conclusion. Unfortunately, not one of these critical functional assessments has been performed in the requisite species. Without these cross-species comparisons, function interpretations must be extracted from a psychophysical literature that is highly skewed toward the horizontal localization of spectrally rich stimuli (for a convenient source of animal psychophysical data, see Fay, R. R., 1988).

Figure 28 presents a sample of the animal psychophysical tests that have used broadband noise to determine localization thresholds in the horizontal plane (Heffner, R.S. and Masterton, R. B., 1990). Results from eight different species are organized according to predator (Figure 28(a)) versus prey lifestyles (Figure 28(b)). Included in the comparison are domestic cats and three of the four prey species where physiological results suggest an impoverished spectral processing pathway (mice, rats, and gerbils). A functional void appears to exist between the subject groups. The most acute sense of direction is limited to predatory species, where there is an evolutionary premium on accurate localization.

The least weasel is a carnivore that feeds on mice and voles (Figure 28(c)). Because it is comparable in size to a mouse or gerbil, head-shadowing effects are expected to produce equivalent ITD and ILD cues. Despite this similarity in binaural acoustics, the small predator's directional hearing is approximately twice as accurate as the localization behaviors of size-matched prey (Heffner, R. S. and Heffner, H. E., 1987). The neuroanatomical source of this advantage has not been explored with electrophysiological or more detailed psychophysical methods. It is intriguing to speculate that the refinements for

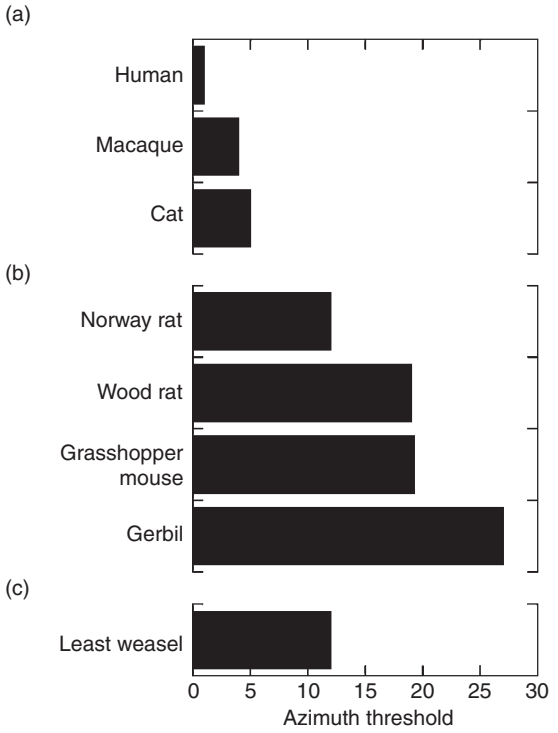

Figure 28 Representative azimuth thresholds for primates and predatory species (a), prey species (b), and a small predator (c). Best thresholds are observed among predatory species. Although the least weasel's head size is equivalent to the mouse and gerbil, the small predator exhibits more accurate localization behaviors. Thresholds were obtained with a variety of psychophysical procedures using noise bursts. The data were compiled by Heffner R. S. and Masterton R. B. (1990).

spectral processing found in the cat contribute to a general enhancement of localization abilities among other predatory species.

This chapter uses the concept of the spectral processing pathway as an organizing principle for the extensive literature on monaural sound localization. Unlike the overt structural underpinnings of the binaural auditory system, the spectral pathway is implied by unusual physiological patterns in the central auditory system of the cat. Many details of these processes remain to be discovered and are likely to change with further elaboration in additional animal models. The lasting value of this construct may be its ability to serve as a theoretical foundation for future studies of the stimulus properties, neural responses, anatomical structures, and species differences that shape directional hearing. For several decades, models of binaural processing have exerted a profound influence on auditory physiology and psychoacoustics (Colburn, H. S., 1973; Jeffress, L. A., 1948). Similar hypothesis-driven research into the role of spectral cues for sound localization is just beginning.

3.38.1 Echolocation Behavior

Echolocation tasks differ according to the type of habitat (e.g., open space vs. dense vegetation) and behavioral goal (obstacle avoidance or localization and identification of small prey). There is a close link between sonar signals, habitat, and demands on cochlear and central auditory processing (review: Neuweiler, G., 1990; Schnitzler, H.-U. *et al.*, 2003). Brief (1–3 ms) broadband downward frequency-modulated (FM) signals or signal components provide precise references for accurate target localization based on the time differences between emitted call and returning echo. They also deliver spectral information about the fine texture of the target. Long (10–60 ms) constant-frequency (CF) signal components are advantageous in detection tasks and for analysis of relative motion. Bats employing long CF-FM calls compensate for the upward Doppler shift in the frequency of echoes that results from their own flight by lowering the frequency of the emitted call. As a consequence, returning echoes are actively clamped at a reference frequency that is slightly higher than the CF emitted at rest. The fine frequency resolution required for this task is provided by a region of strongly enhanced tuning in the audiogram. This region also serves to specifically analyze small rhythmic modulations in amplitude and frequency of the echoes that are reflected from fluttering wings of insects. Doppler-sensitive sonar was independently evolved in old-world horseshoe bats, and in one species of new-world phyllostomid bats, the mustached bat (*Pteronotus parnelli*) as an adaptation for hunting insects in dense vegetation. Remarkably, the specialized filtering mechanism for the preferred echo frequency is not a product of central auditory processing but resides in the sensory organ, the cochlea (review: Neuweiler, G., 1990; Schnitzler, H.-U. *et al.*, 2003).

3.38.2 Cochlear Physiology

Pollak G. D. *et al.* (1972) published a seminal paper on specialized cochlear processing in the mustached bat. At frequencies of about 62 kHz coinciding with the frequency range of the second harmonic CF component, there is a sharply tuned threshold minimum in the cochlear microphonic (CM) potential, and thresholds on both sides of the best frequency increase with slopes of up to 210 dB kHz^{-1}, sharper tuning than in any other vertebrate ear. At this frequency, the CM shows a pronounced nonlinearity and ringing after the offset of the acoustic stimulus (Figure 1), which is indicative of the presence of an exceptionally sharply tuned mechanical resonance. Sharp tuning and resonance were shown to be physiologically vulnerable (review: Kössl, M. and Vater, M., 1995).

Shortly after the discovery of otoacoustic emissions in humans, and the discovery of active motility of outer hair cells (OHCs) that provide the basis for the concept of an active cochlear amplifier (review: Dallos, P., 1992), it was found that the mustached bat ear routinely emits a single evoked otoacoustic emission at about 61 kHz whose amplitude is about 100 times stronger than in other mammals. Occasionally, this evoked emission becomes a strong spontaneous otoacoustic emission at the same frequency (review: Kössl, M. and Vater, M., 1995; Kössl, M., 1997). The mammalian cochlear amplifier thus is functional even at ultrasonic frequencies.

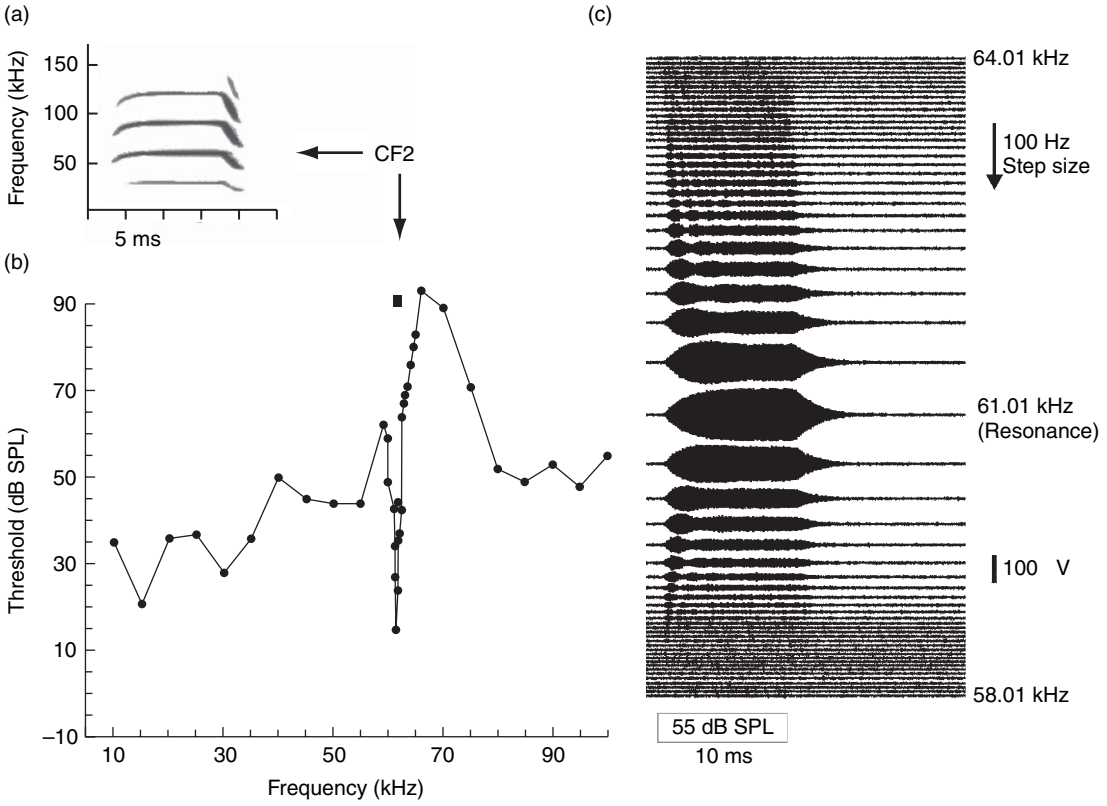

Figure 1 (a) Echolocation call of the mustached bat. (b) Cochlear microphonic threshold curve. (c) Cochlear microphonic resonance (b and c: Kössl, M. *et al.*, 2003).

CM recordings in horseshoe bats reveal sharp cochlear tuning to the CF but a less pronounced resonance, and only a weak expression of otoacoustic emissions suggesting that the specialized tuning mechanisms differ in detail. Measurements of distortion product otoacoustic emissions in CF-FM bats provide further evidence for the hydromechanical nature of sharp tuning, the contribution of nonlinear cochlear amplification, and a second filter mechanism based on filter properties of the tectorial membrane (TM) (review: Kössl, M., 1997).

With a laser diode interferometer, Kössl M. and Russell I. J. (1995) measured sensitive basilar membrane (BM) displacement in the basal cochlear turn of the mustached bat and found strong resonant oscillations at about 61 kHz that critically depended on the physiological state of the cochlea. A maximum Q10 dB value of 610 for BM tuning is a record among mammals and sharper than reported neuronal tuning in the bat.

Cochlear frequency mapping in horseshoe bats and mustached bats reveals that a narrow frequency band around the dominant CF component has an expanded representation in BM length with mapping coefficients >50 mm per octave as compared with the values of 3 mm per octave in nonspecialized mammals (Figure 2; review: Kössl, M. and Vater, M., 1995; Kössl, M., 1997). The expanded frequency representation within a cochlear region of maximal innervation density results in a vast overrepresentation of a narrow frequency band in the central auditory pathway. This frequency band contains neurons that are exceptionally sharply tuned (Q10 dB values up to 300 as compared with values of about 20 in other vertebrates). Thus, an auditory fovea is created for analysis of the biologically most important frequencies.

3.38.3 Cochlear Anatomy

Emphasizing the importance of hearing, extant microchiropteran bats are characterized by an enlarged cochlea. This character dates back at least 50 million years as evidenced by the oldest known fossil bat, *Icaronycteris index* (review: Springer, M. S. *et al.*,

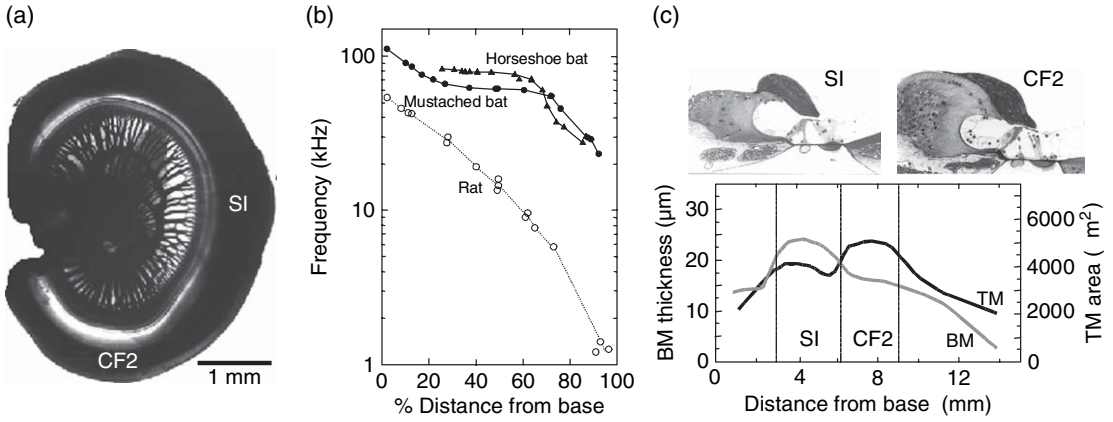

Figure 2 (a) Surface view of the basal turn of the mustached bat cochlea with densely innervated zone at the representation place of CF2 and more basally located sparsely innervated (SI) zone. (b) Cochlear frequency maps of horseshoe bats (Kössl, M. and Vater, M., 1985a; 1985b) and mustached bats (Kössl, M. and Vater, M., 1985a; 1985b) in comparison with the rat (Müller, M., 1991). (c) Cross sections of the organ of Corti in the SI and CF2 zones of the mustached bat cochlea and basoapical changes in basilar membrane (BM) thickness and tectorial membrane (TM) area (Vater, M. and Kössl, M., 1996).

2001). Cochlear size reaches maximal values in species that employ Doppler-sensitive sonar, and among different species of horseshoe bats, there is a clear correlation between the diameter of the basal cochlear turn and the frequency of the CF component (review: Kössl, M. and Vater, M., 1995; Vater, M., 1998; 2000).

The basic anatomical design of the bat cochlea follows the scheme common to all marsupial and placental mammals as evidenced by light microscopic, scanning electron, and transmission electron microscopic studies (review: Kössl, M. and Vater, M., 1995; Vater, M., 1998).

There is the same set of sensory and nonsensory structures as in nonecholocating mammals. There is one row of inner hair cells (IHCs) separated by pillar cells from the three rows of OHCs. Each OHC is supported by a Deiters' cell, and the lateral membrane of OHCs is surrounded by the spaces of Nuel. In mustached bats, the presence of prestin in OHC was demonstrated with immunocytochemical techniques. As in other mammals, IHCs receive the bulk of afferent innervation. Lateral and medial olivocochlear efferent systems are established in bats, but as a remarkable specialization, whose functional consequences still need to be resolved, OHCs of horseshoe bats completely lack efferent innervation.

Within the general mammalian scheme, bats show specializations for high-frequency hearing: short OHCs, small stereovilli, and a thick and narrow BM (review: Kössl, M. and Vater, M., 1995; Vater, M., 1998). Unlike in all other mammals, CF-FM bat cochleae have prominent maxima and minima in afferent innervation density within the basal cochlear turn, and profound specializations in the basoapical gradients in the morphology of the BM and the TM that appear to be related to exceptionally sharp tuning properties to the dominant CF signal. Bats have additional species-specific specializations. The mustached bat cochlea exhibits pronounced changes in scale volume of the basal turn, and the horseshoe bat cochlea features a specialized secondary spiral lamina.

Within the auditory fovea of the mustached bat, there are multiple morphological specializations (Figure 2). It can be subdivided into a basal and an apical part by a sharp transition (occurring within a few hundred micrometers) in morphological parameters such as innervation density and morphology of the TM and the BM. In the basal part of the fovea, innervation density is low, the BM is prominently thickened, and the TM is club shaped. In the densely innervated apical part of the fovea, the BM is not specialized, but the TM is enlarged with an extensive attachment to the spiral limbus.

3.38.4 Cochlear Development

Studies of the postnatal development of echolocation and audition in horseshoe bats (Rübsamen, R. and Schäfer, M., 1990) and mustached bats (Kössl, M. *et al.*, 2003; Russell, I. J. *et al.*, 2003) have revealed a concomitant upward shift in the frequency of the CF component and the tuning of the auditory fovea. Thus, bats seem to monitor a postnatal shift in the

cochlear frequency map in the pitch of their voice. CM recordings in young mustached bats also reveal the developmental sharpening of tuning over the first 3 postnatal weeks (Kössl, M. *et al*., 2003). Cochlear dimensions and the main morphological specializations of the BM and TM are established at birth in CF-FM bats, but subtle structural changes indicate postnatal increases in stiffness of the micromechanical system (review: Vater, M., 2000).

3.38.5 Cochlear Mechanisms

There is strong evidence for a labile, actively controlled mechanical resonator in the cochlea of the mustached bat that is tuned to 61 kHz, the frequency of the dominant component of the Doppler-shifted echo. This mechanism is superimposed on the conventional mechanisms common to all mammals. The active elements are represented by the OHCs that provide feedback to the passive mechanical system, as they do in other mammals. Unlike in other mammals, feedback through OHCs in these bats is further enhanced by a highly tuned passive resonator that is contained in the morphological specializations of BM and TM. Collating data from anatomy, frequency mapping, BM displacement measurements, and measurements of distortion product otoacoustic emissions, Russell I. J. and Kössl M. (1999) proposed a model for the mustached bat cochlea that involves (1) buildup of resonant oscillation in form of a standing wave on the TM in the basal part of the fovea; (2) transfer of resonant energy into the organ of Corti and BM of the more apical parts of the fovea, where IHCs are most densely innervated and receive a boosted 61 kHz mechanical stimulation; and (3) OHCs that are essential to enhance, fine-tune, and control the resonance.

3.39.1 Introduction

Roughly 210–250 million years ago, three vertebrate clades had evolved means to perceive airborne sound, that is, ears that feature a tympanic membrane and a middle ear cavity. This evolutionary milestone occurred independently within anurans, reptiles (including archosaurs, the ancestors of birds), and early mammals (Clack, J. A., 1997; 2002). In order to process sensory information that derived from auditory end organs, respective central neural structures evolved in parallel. That is, either novel neural circuits were created to serve auditory computation or, alternatively, existing precursor nuclei (unspecific

or freed from serving other senses, respectively) had differentiated to support the analyses of acoustic cues (Grothe, B. *et al.*, 2004).

Evidently, the central extraction of features that indicate the nature and whereabouts (what and where) of sound sources was vital for all hearing animals. Limited acoustic cues are available to compute that source-specific information within the brain: the temporal and spectral pattern of an incoming sound, for instance, can hint to the nature of its source. The location of a sound source is reflected by level, time, and spectral disparities at the two ears that receive sound traveling along different trajectories (Irvine, D. R., 1992; Grothe, B., 2003). Within that well-defined framework of physical constraints, anurans, reptiles, and early mammals independently evolved neural solutions to process and represent acoustic objects. Consequently, auditory systems of different vertebrate classes express – particularly at early stages of the auditory pathway – striking functional, anatomical, morphological, and biophysical similarities (Grothe, B. *et al.*, 2004). A functional analogy in the context of temporal processing is reflected, for instance, by the modern avian nucleus laminaris (NL) and the mammalian medial superior olive (MSO; Figure 1). Both brainstem structures are best known for their potential to process interaural time differences (ITDs), and are characterized by regularly arranged bipolar cells with highly reminiscent input patterns, and highly specialized membrane properties (Grothe, B., 2003). In both nuclei, these principal cells receive precisely timed binaural input from bushy cells of the nucleus magnocellularis, and its mammalian equivalent, the anteroventral cochlear nucleus (AVCN), respectively. The projections were shown to promote coincident input detection within the principal cells of the NL and the MSO. So, on first glance the concepts of neural computation appeared identical within the two structures. However, recent physiological and theoretical studies (Brand, A. *et al.*, 2002; Harper, N. S. and McAlpine, D., 2004) indicate that the rules of neural processing applied within the NL and the MSO, respectively, differ. This concerns particularly inhibitory inputs that seem to be involved in shaping neural ITD functions in mammals, other than in birds where inhibitory inputs help to shunt the membrane potential in order to provide gain control (compare also Howard, M. A. *et al.*, 2007). Moreover, two different neural codes of azimuthal space were observed, a so-called place code in birds (Konishi, M., 2003) and a hemispheric population code in mammals (McAlpine, D. *et al.*, 2001), seem to be realized. The NL/MSO circuits now epitomize independently evolving neural structures that were forged by converging evolutionary pressures (Carr, C. E. and Soares, D., 2002). Research on the development of their respective rules of computation (Agmon-Snir, H. *et al.*, 1998; Cramer, K. S. *et al.*, 2002; Kapfer, C. *et al.*, 2002) further established the NL/MSO as an outstanding model system for a stringent investigation of the independent evolution of functionally analogous neural circuits on the molecular, cellular, and systemic level.

The MSO also provides, as one of very few structures, additional opportunities to study the parallel evolution within the class of mammals – by means of comparing its appearance in both acoustically specialized and nonspecialized mammalian species. Mammals have conquered a great number of ecological niches that embody a great variety of acoustic environments. But not all mammals make use of ITDs to localize low-frequency sounds. In fact, the audiogram of most mammals does not even encompass frequencies that make ITD coding useful for sound localization (i.e., in mammals, frequencies below ~2 kHz). ITD coding might therefore be considered to represent only one of several possible specializations of the MSO (in this case for low-frequency sound localization). Over a common mammalian hearing range between 4 and 40 kHz, however, interaural level differences (ILDs) are far more efficient to encode the location of a sound source (Tollin, D. J., 2003). (Note that the most primitive mammals, monotremes, which possess a middle ear strikingly similar to that of early mammals, exhibited good hearing only from 4 to 18 kHz, apparently the original mammalian range of hearing (Mills, D. M. and Shepherd, R. K., 2001) before it was extended to frequencies typically up to 40 kHz. Low-frequency hearing, therefore, has to be viewed as a late adaptation in mammals.) So it appears that the universal feature of MSO cells – whether concerned with ITD processing or not – could be precise temporal processing itself. This computational capacity, modified to various degrees, can support diverse species-specific purposes like low-frequency sound localization or high-frequency sound pattern recognition. Indeed, the MSO expresses a high degree of morphological and functional plasticity across present mammalian species (Figure 2; Grothe, B. and Neuweiler, G., 2000). Both inhibitory and excitatory inputs to the MSO seem adaptable, and reflect the structure's adjustment to individual ecological constraints (Covey, E. *et al.*, 1991; Kapfer, C. *et al.*,

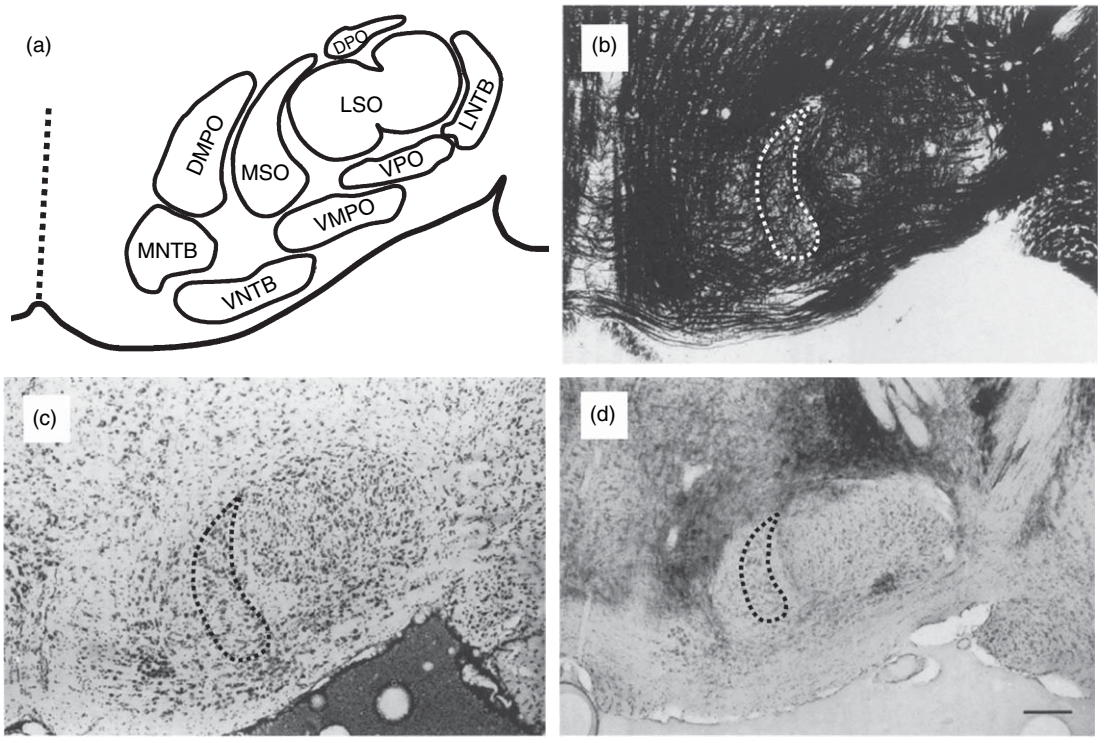

Figure 1 (a) Outline of the Mexican free-tailed bat SOC and MSO illustrated in fiber staining (b), Nissl staining (c), and acetylcholinesterase staining (d). Calibration bar = 200 μm. DMPO, dorsomedial periolivary nucleus; DPO, dorsal periolivary nucleus; LNTB, lateral nucleus of the trapezoid body; LSO, lateral superior olive; MNTB, medial nucleus of the trapezoid body; MSO, medial superior olive; SOC, superior olivary complex; VMPO, ventromedial periolivary nucleus; VNTB, ventral nucleus of the trapezoid body; VPO, ventral periolivary nucleus. Adapted from Grothe, B., Schweizer, H., Pollak, G. D., Schuller, G., and Rosemann, C. 1994. Anatomy and projection patterns of the superior olivary complex in the Mexican free-tailed bat, *Tadarida brasiliensis mexicana*. J. Comp. Neurol. 343, 630–646.

2002; Kandler, K., 2004). Acoustic constraints, in particular, are likely to have profoundly influenced the phylogenesis of the auditory brainstem of bat species with foraging strategies that rely on the auditory system. For neuroscience, therefore, the bat MSO represents a useful model system to study the evolution of a distinct neural circuit in well-defined ecological niches.

3.39.2 The Medial Superior Olive of Normal Low-Frequency Hearing Mammals

The MSO is part of the superior olivary complex (SOC; exemplified for the Mexican free-tailed bat in Figure 1) and is among the first stages in the ascending auditory pathway that integrate binaural inputs. With regard to low-frequency sound localization in dogs and cats (Goldberg, J. M. and Brown, P. B., 1969; Yin, T. C. and Chan, J. C., 1990) the MSO has traditionally been viewed as a coincidence detector that analyses ITDs: schematically, MSO cells cross-correlate phase-coupled binaural inputs, and generate a spike rate that depends on interaural phase differences (IPDs; Jeffress, L. A. and Robinson, D. E., 1962; Blauert, J. and Lindemann, W., 1986; Caird, D. and Klinke, R., 1987; Wightman, F. L. and Kistler, D. J., 1992; Macpherson, E. A. and Middlebrooks, J. C., 2002; Yin, T. C., 2002). These binaural phase disparities reflect the ITDs caused by acoustic path length differences as a sound reaches both ears, and they vary systematically with the location of a sound source relative to a listener. In agreement with Jeffress' elegant delay line model (Jeffress, L. A., 1948), a position-dependent IPD was postulated to coincidentally excite a distinct subset of MSO neurons – owing to an inverse arrangement of incoming axon path lengths. As a whole, the coincidence detector neurons demonstrated in the MSO were thought to create a place code of azimuthal space within each frequency band.

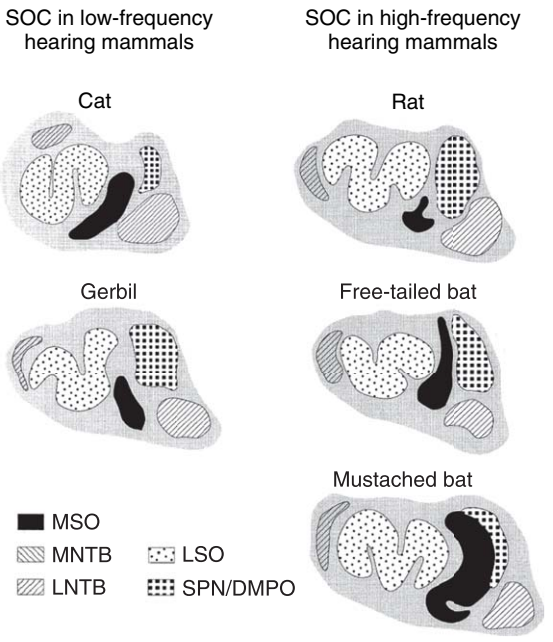

Figure 2 The outline of the MSO in several mammals as apparent from transversal sections. DMPO, dorsomedial periolivary nucleus (nonrodents); LNTB, lateral nucleus of the trapezoid body; LSO, lateral superior olive; MNTB, medial nucleus of the trapezoid body; MSO, medial superior olive; SPN, superior paraolivary nucleus (rodents). From Grothe, B. 2000. The evolution of temporal processing in the medical superior olive, an auditory brainstem structure. Prog. Neurobiol. 61, 581-610.

This view of the MSO was in line with early anatomical studies in dogs and cats that feature a prominent MSO. These animals possess bipolar principal MSO cells that are arranged in an orderly column with dendrites oriented mediolaterally (Stotler, W. A., 1953; Goldberg, J. M. and Brown, P. B., 1968). The functional significance of the MSO for sound localization was later supported by a combination of results. First, Conlee, J. W. *et al.*, (1984; 1986) typified an atrophic MSO in albino cats. Second, Heffner R. S. and Heffner H. E. (1987) gave evidence about behavioral deficits of albino cats in azimuthal sound localization. In accord with this behavioral data, a physiological study indicated a decreased ITD sensitivity within the albino cat brainstem (Yin, T. C. *et al.*, 1990). However, despite some evidence of a systematic arrangement of delay lines that could cover ITDs experienced across azimuthal space (Smith, P. H. *et al.*, 1993), the classical picture of the MSO as a pure Jeffress-type coincidence detector could neither be confirmed nor be rejected based on anatomical data.

Still, it remained conceptually fitting that the tonotopic projections to the MSO have been shown to be biased in dogs and cats, leading to a strong representation of low sound frequencies known to be predominantly localized by means of ITD (Goldberg, J. M. and Brown, P. B., 1969; Guinan, J. J. Jr., *et al.*, 1972). Also, single-unit recordings in the MSO of cats (Galambos, R. *et al.*, 1959; Caird, D. and Klinke, R., 1983; Yin, T. C. and Chan, J. C., 1990) and dogs (Goldberg, J. M. and Brown, P. B., 1969), as well as gerbils (Spitzer, M. W. and Semple, M. N., 1995; Brand, A. *et al.*, 2002), have established that most MSO neurons in low-frequency hearing animals can be excited by monaural acoustic stimulation at either ear. This response property is in line with the view of an MSO that performs neural computation on the basis of excitatory inputs from both ears. These projections augment the analysis of ITDs based on coincidence detection by maintaining or even enhancing precisely phase-coupled discharges of auditory nerve (AN) fibers (Galambos, R. and Davis, H., 1943; Kiang, N. Y. *et al.*, 1965; Rose, J. E. *et al.*, 1967; Joris, P. X. *et al.*, 1994a; 1994b), and were shown to originate in spherical bushy cells (SBC) of the ventral cochlear nucleus (VCN) (Warr, W. B., 1966; Osen, K. K., 1969; Lindsey, B. G., 1975; Smith, P. H. *et al.*, 1993; Kitzes, L. M. *et al.*, 1995).

In extension of the classical view of the MSO as a comparator structure of excitatory inputs, strong glycinergic inhibitory inputs exist that derive from the medial and lateral nuclei of the trapezoid body (MNTB; LNTB; Figure 3; Clark, G. M., 1969; Perkins, R. E., 1973; Cant, N. B., 1991; Cant, N. B. and Hyson, R. L., 1992; Kuwabara, N. and Zook, J. M., 1992). Pharmacological studies had shown that glycinergic inhibition alters the response properties of MSO neurons in gerbil slice preparations (Grothe, B. and Sanes, D. H., 1993; 1994). More recently, indirect evidence for inhibition being involved in ITD processing in the SOC came from awake rabbit recordings (Batra, R. *et al.*, 1997). In gerbils, glycinergic projections had been shown to be crucial to the MSO cells' ITD sensitivity *in vivo* (Brand, A. *et al.*, 2002). (Note gerbils are small desert rodents that depend on far-reaching low-frequency sound localization to avoid predation. To this end, extreme ITDs in the low microsecond range must suffice due to the animals' head size.)

So clearly, in low-frequency hearing mammals, the MSO encodes favorable ITDs by facilitated spike rates (Yin, T. C. and Chan, J. C., 1990; Spitzer, M. W. and Semple, M. N., 1995). Furthermore,

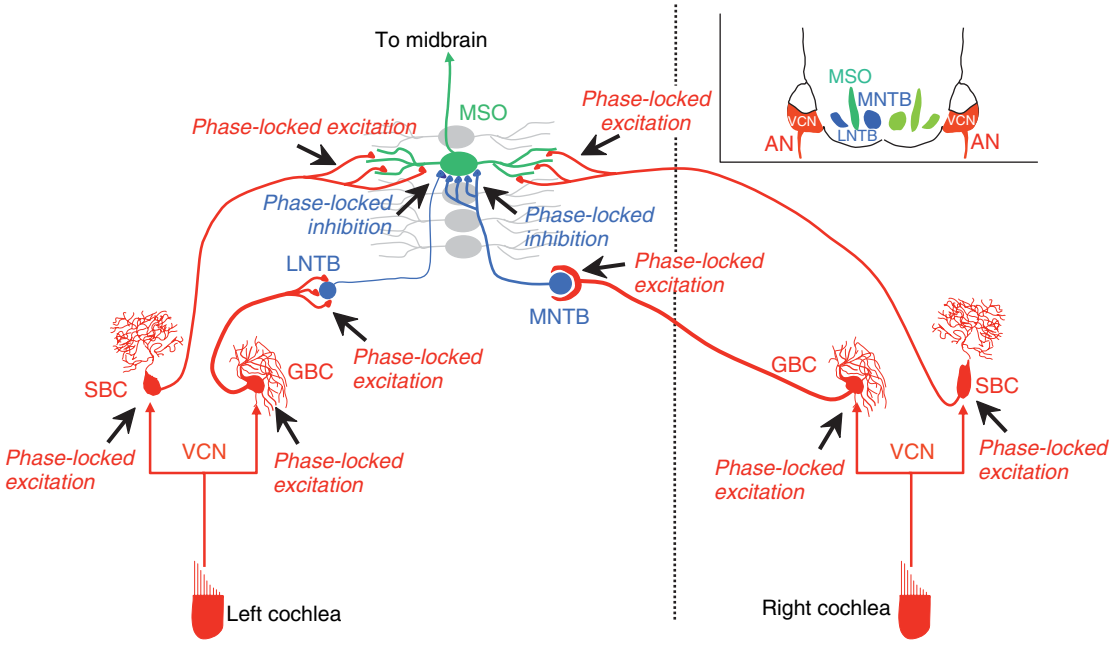

Figure 3 The mammalian ITD encoder is the MSO, an auditory brainstem structure (inset). MSO neurons are bipolar and their somata are arranged in one parasagittal plane. Excitatory projections originate from the left and right cochlea. Auditory nerve fiber discharges time-lock to the stimulus onset or phase-lock to ongoing pure tones up to about 2 kHz. They excite spherical and globular bushy cells, respectively, in the VCN. SBCs and GBCs also provide phase-locked excitation to their targets: SBCs project to the MSO on both sides, GBCs to the contralateral MNTB and the ipsilateral LNTB. The inputs to the MNTB and LNTB are specialized to preserve temporal information: the MNTB is driven by a gigantic synapse, the calyx of Held. MNTB and LNTB neurons provide phase-locked, glycinergic, hyperpolarizing inhibition to the ipsilateral MSO. MSO neurons extract the ITD from a comparison of their four inputs and project to higher auditory centers. The well-timed inhibition is crucial for adjusting the ITD sensitivity of MSO cells to the physiologically relevant range of ITDs. AN, auditory nerve; GBC, globular bushy cells; ITD, interaural intensity difference; LNTB, lateral nucleus of the trapezoid body; MNTB, medial nucleus of the trapezoid body; MSO, medial superior olive; SBC, spherical bushy cells; VCN, ventral cochlear nucleus. several authors have demonstrated that the best IPD of an MSO unit could be predicted by the phase angle of its responses to monaural stimulation. It was also established that the best response of an MSO neuron was stable at a certain ITD across different stimulus frequencies (Figure 4(a)). All of these results support the view that the function of the MSO in low-frequency hearing mammals is to encode the azimuthal origin of low-frequency sounds by coincidence detection of binaural inputs. In remarkable contrast to avian ITD coding, however, this view had to be expanded recently in an unexpected way: The adjustment of the MSO sensitivity to the behavioral range of ITDs in gerbils seems to be accomplished by experience-driven refinement of inhibitory inputs (Brand, A. *et al.*, 2002; Kapfer, C. *et al.*, 2002; Grothe, B., 2003). During auditory maturation, the compound postsynaptic timing of these inhibitory projections is enhanced by the concentration of glycinergic synapses onto the soma of an MSO cell (Magnusson, A. K. *et al.*, 2005). As a result, binaural excitatory and mainly contralateral inhibitory inputs appear to shape a composite ITD function in MSO neurons. Interfering with this development by keeping animals in omnidirectional broadband noise for several days after hearing onset reduces the refinement of the inhibitory inputs (Kapfer, C. *et al.* 2002), and causes an abnormal ITD tuning (Seidl, A. H. and Grothe, B., 2005). One possible scenario is that inhibition precedes contralateral excitation at a given sound frequency: this phase shift determines a narrow time window during which an MSO cell can respond to coincident binaural excitation, and so tunes the maximal slope of ITD functions in the gerbil MSO to behaviorally relevant ITDs (Figure 4(b)). Therefore, a negative correlation between an MSO neuron's BF and its best ITD would result from the phase-coupled interaction of excitatory and inhibitory inputs (compare McAlpine, D. *et al.*, 2001). Analogous observations were recently made in larger

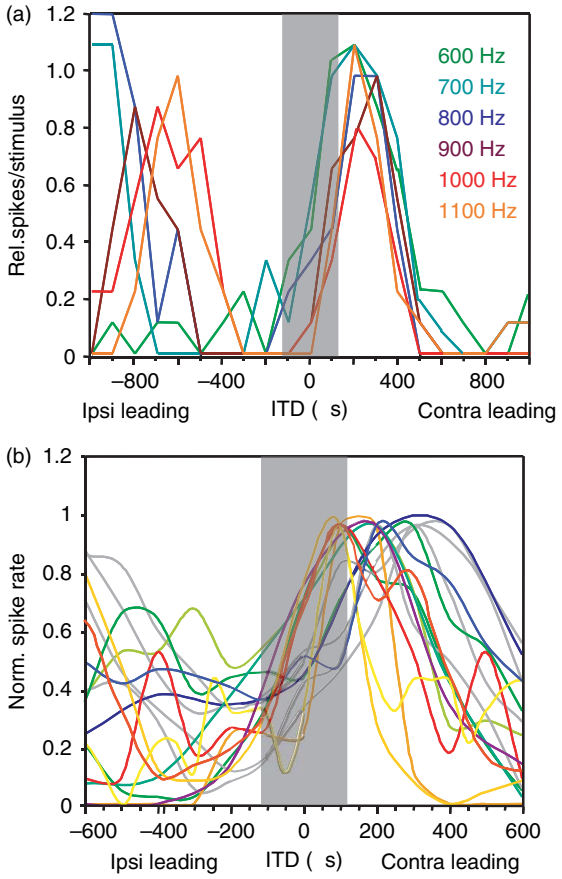

Figure 4 ITD coding in the mammalian MSO. (a) ITD function of a gerbil MSO neuron, tested with pure tones at different frequencies. As is typical, the peak ITD is independent of the stimulus frequency. The gray area indicates the physiologically relevant range for gerbils (±120 μs). (b) ITD functions of gerbil MSO neurons, each tested at its best frequency, 20 dB above threshold. Note that the peaks of ITD functions are largely outside the physiologically relevant range (gray area). The steep slopes of the ITD functions are within the relevant area. ITD, interaural time difference; MSO, medial superior olive. From Brand, A., Behrend, O., Marquardt, T., McAlpine, D., and Grothe, B. 2002. Precise inhibition is essential for microsecond interaural time difference coding. Nature 417, 543–547.

mammals with good low-frequency hearing (Hancock, K. E. and Delgutte, B., 2004). One might speculate the dazzling temporal resolution of ITDs in many low-frequency hearing mammals could be produced by similar rules of computation in an MSO that, potentially, refines coincident input detection properties by precisely adjusted and fast inhibition.

By and large, there remains little doubt about the function of the MSO as a coincidence detector that resolves ITDs in some low-frequency-hearing mammals. That said, the long-standing concept of how ITDs are neurally encoded in mammals might have to be revised in some measure to account for the role of surprisingly plastic, and potentially fast, inhibitory inputs to the MSO.

3.39.3 The Medial Superior Olive of Normal High-Frequency Hearing Mammals

Notably, even in low-frequency hearing mammals that use ITDs, up to one third of the units within the MSO do not show classical binaural excitation (Goldberg, J. M. and Brown, P. B., 1969; Yin, T. C. and Chan, J. C., 1990). Recent studies in the avian NL have indicated that this substantial neuronal subset might be overemphasized by biased sampling, since coincident detector unit activity might often remain unnoticed in extracellular recordings (Kuba, H. *et al.*, 2006). On the other hand, anatomical and physiological data on MSO cells from several bat species (discussed below) also suggest a significant presence of nonclassical MSO neurons that lack binaural excitatory input needed for the analyses of acoustic ITDs by coincidence detection. Given that the MSO had initially evolved as an ITD detector for airborne sound, such units would seem somewhat out of place. But very likely the evolutionary development of the MSO was shaped by an early auditory periphery whose transmission of low-frequency sound was limited (Mills, D. M. and Shepherd, R. K., 2001; reviews: Grothe, B., 2000; Grothe, B. *et al.* 2004). Almost certainly, the common ancestors of monotremes and therian mammals developed a three-ossicle middle ear independently from the avian one-ossicle middle ear. Whereas the latter is only suited for low-frequency hearing, the former was initially suited for rather high-frequency transmission (Fleischer, G., 1978; Mills, D. M. and Shepherd, R. K., 2001; Clack, J. A. and Allin, E., 2004; Grothe, B. *et al.*, 2004; Manley, G. A. and Clack, J. A., 2004). The middle ear structure of the early mammalian middle ear was nearly identical to that of recent monotremes or some opossums (Gregory, W. K., 1929; Rosowski, J. J., 1992), and these animals' frequency resolution could therefore approximate the auditory range postulated for early mammals (i.e., above 4–6 kHz; Frost, S. B. and Masterson, R. B., 1994; Mills, D. M. and Shepherd, R. K., 2001). This would suggest that ITD processing capacities were biologically irrelevant for

early mammals, and became relevant only after the onset of effective low-frequency sound transmission. Consequently, comparative studies on the MSO of high-frequency hearing animals were poised to yield substantial data on the origin of this neural circuit, and mechanisms of its functional evolution.

Early on, it was speculated that high-frequency hearing animals – using mainly ILDs for sound localization – do not even possess an MSO (Harrison, J. M. and Irving, R., 1966; Irving, R. and Harrison, J. M., 1967). In retrospect, this exclusive perception of the MSO as an ITD-coding structure in low-frequency-hearing mammals might have been premature: in unison with its counterpart, the lateral superior olive (LSO; Tollin, D. J., 2003), the MSO was too firmly embedded in the framework of the duplex theory of sound localization (Rayleigh, L., 1907; Masterson, B. and Diamond, I. T., 1967). Now that the resolution of low-frequency sound in itself might be viewed as a secondary adaptation in mammals, however, the classical MSO could become a rather special case. To learn more about the putative original function of early MSO cells, more comparative investigations of the MSO in high-frequency hearing animals like small opossums, rats, and mice are needed. These animals might share, to some extent, an ancient auditory system, and respective studies aptly complemented the understanding of the MSO's evolution in auditory specialists like gerbils and bats.

To date, only a few MSO-like structures have been described in normal high-frequency hearing animals, like rats (compare Figure 2; Rogowski, B. A. and Feng, A. S., 1981), opossums (Willard, F. H. and Martin, G. F., 1983; 1984), and mice (Franklin, K. B. and Paxinos, G., 1997). Interestingly, in high-frequency-hearing mammals the somata of typical bipolar MSO cells are arranged in a less orderly fashion, which indicates that the neural arrangement is rather critical to ITD specialists (Grothe, B. *et al.*, 2004). Still, a column-like arrangement of cells could be made out in rats (Feng, A. S. and Rogowski, B. A., 1980; Rogowski, B. A. and Feng, A. S., 1981). The cellular morphology of this subset of MSO units seemed nearly identical to that of bipolar fusiform principal neurons found in low-frequency hearing animals.

In line with high-frequency sound localization concepts, however, neurophysiological recordings in the albino rat MSO provided little indication that the nucleus might process ITDs, and no biologically relevant ITD sensitivity to pure tones was revealed (Inbody, S. B. and Feng, A. S., 1981). Still considerable, one half of the units in the rat MSO displayed binaural excitatory inputs, while the other half received purely inhibitory projections from the ipsilateral ear. As for the ITD-user gerbil, evidence for glycinergic inhibitory inputs to the MSO of rat and opossums was provided by Kapfer C. *et al.* (2002). This suggests that binaural excitation and inhibition (via the LNTB and the MNTB) belong to the ancient set of MSO inputs regardless of whether the animals are enabled to resolve extreme ITDs or not. A striking difference, however, concerns the refinement of glycinergic inputs to the soma of MSO cells observed in cats, ferrets, and gerbils: in the high-frequency hearing opossum and rat, glycinergic inputs do not seem to be refined but rather are distributed across the soma and dendrites.

So far, it remains open what sound parameters the MSO of opossums, rats, and mice might preferentially process. Studies on the MSO of rats indicate that the units serve functions other than ITD processing (Feng, A. S. and Rogowski, B. A., 1980; Rogowski, B. A. and Feng, A. S., 1981). The results in rats come from albinos, however, that show deficits in ITD processing (see above). Still, rat MSO neurons displayed a significant sensitivity to ILDs – a feat usually attributed to the neighboring LSO – which implies that the rat MSO could contribute to spatial integration of high-frequency sounds. As it stands, assuming that the rat MSO preserves some characteristics of an early mammalian MSO precursor, its original function could not be linked to ITD processing. Still, the classical input combination of potentially well-timed excitatory and inhibitory projections to the rat MSO suggests that the neural circuit might serve – in a more general sense – temporal computation. Note that other than pure tones, natural envelope-modulated sounds promote tightly coupled neural firing patterns that could promote acoustic pattern recognition, echo suppression, and ILD coding (Tollin, D. J., 2003). Studies on other high-frequency hearing mammals, namely bats (see below), have indicated that a principally similar MSO circuit design supports either task (Grothe, B. *et al.*, 1997; Grothe, B. and Neuweiler, G., 2000).

High-frequency hearing nonspecialists have helped to establish the anatomy, cell morphology, and inputs of an MSO that might still largely resemble a putative precursor structure in early mammals who shared similar auditory experiences (determined by, e.g., the head size, audiogram, and habitat). On the

whole, mammals without or with weakly developed low-frequency hearing that may not use ITDs for sound localization possess an anatomically less highly ordered MSO. The function of the MSO in these animals remains obscure. Even so, studies on bats have indicated putative functions of the MSO in high-frequency hearing animals, and are reviewed in the following section.

3.39.4 The Medial Superior Olive of Bats

Bats have evolved a range of hunting strategies, based in part on echolocation (Neuweiler, G., 1990). By means of auditory analysis, the animals are capable of both active and passive prey discrimination, recognition, and localization. In the bat model system behaviorally relevant auditory signals could be inferred from emitted echolocation calls and received echo patterns, respectively (Figure 5). Species-specific discrimination, recognition, and localization parameters were pinned down by psychophysical experiments (Neuweiler, G., 2000). So defined acoustic parameters could then be implemented in physiological research on the bat MSO. Thereby, stimulus paradigms were well matched to the animal's central auditory filter properties. A great amount of information was extracted with respect to MSO coding properties within bat animal models,

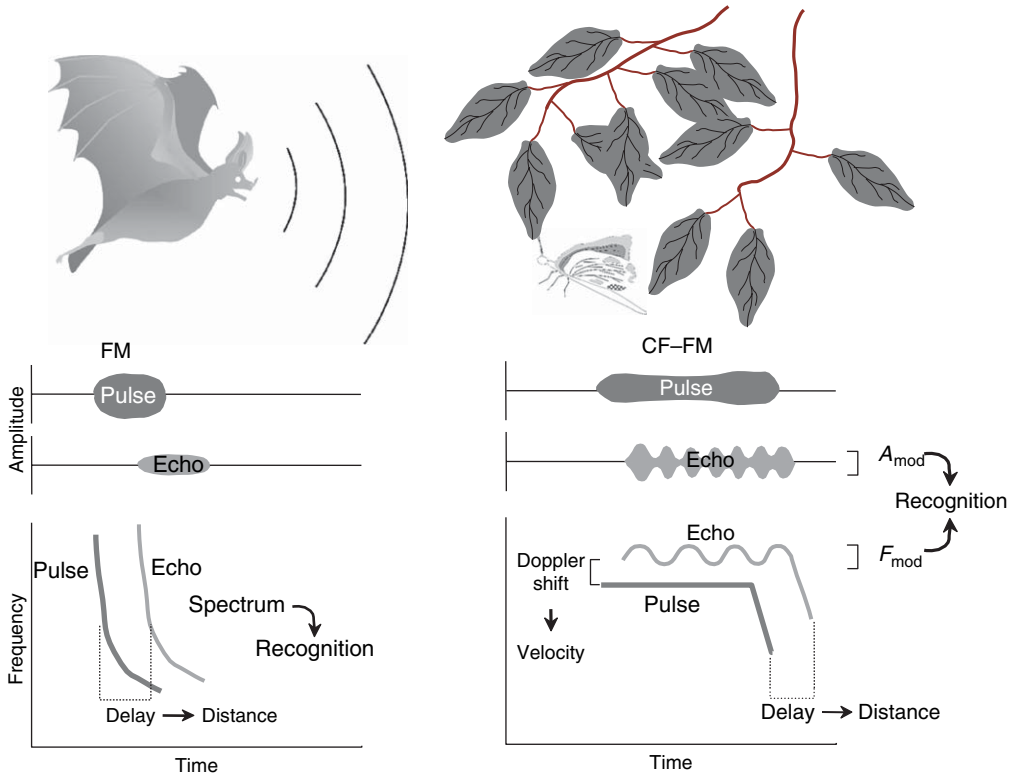

Figure 5 Two different echolocation strategies of insectivorous bats hunting for flying insects. Most bats emit downward FM sweeps of a few milliseconds' duration (left panels). Spectral changes in the echo compared to the pulse itself contain information about the object, the echo delay about the object distance. Using this echolocation call it is difficult to distinguish objects from background in dense foliage. Some bats specialized for hunting in dense foliage use a combination of an FM sweep for distance measurement and a CF component for prey recognition (right panels). CF components can last up to 80 ms. When reflected from a fluttering target the CF component in the echo is modulated in frequency and amplitude according to the insects' wing beat frequency. Doppler shifts in the CF component contain additional information about the relative velocity of the target. The upper panels give the oscillogram (time vs amplitude) of pulse (black) and echo (gray). The lower panels display the frequency changes in the echo (time vs frequency). CF, constant frequency; FM, frequency modulated. From Grothe, B. 2000. The evolution of temporal processing in the medial superior olive, an auditory brainstem structure. Prog. Neurobiol. 61, 581–610.

and the evolution of habitat-specific modifications of the MSO could be described in a number of species that showed different levels of specialization.

3.39.4.1 Anatomy of the Medial Superior Olive in Bats

3.39.4.1.1 Frequency-modulated bats

The most representative group of the microchiroptera are so-called FM bats, which use frequency-modulated (FM) echolocation calls to orient and, in most bats, catch flying insect prey. The Mexican free-tailed bat *Tadarida brasiliensis mexicana* (Grothe, B. *et al.*, 1994), the big brown bat *Eptesicus fuscus* (Covey, E. and Casseday, J. H., 1995), and the velvety free-tailed bat *Molossus ater* (Harnischfeger, G. *et al.*, 1985) were all shown to possess an MSO homologous to the MSO of normal mammals. First, the relative position of the MSO within the SOC was not altered in these species (Covey, E. and Casseday, J. H., 1995). Second, the MSO was distinct from adjacent periolivary nuclei (Schofield, B. R., 1991) by its absence of ACh-positive cells (compare Figure 1(d); Grothe, B. *et al.*, 1994). Thirdly, a low immunoreactivity for GABA and glycine has set the MSO apart from neighboring structures (Fubara, B. M. *et al.*, 1996). Fourthly, the principal cells of the MSO were of bipolar morphology, growing dendrites both medially and laterally (Grothe, B. *et al.*, 1994), although not arranged in the typical one-cell column as in low-frequency-hearing animals. In conclusion, the MSO anatomy of these bats (henceforth called *Tadarida*, *Eptesicus*, and *Molossus)* deviated little from that found in other high-frequency hearing animals. Note that not all mentioned criteria were investigated in each bat species, however.

3.39.4.1.2 Constant-frequency–frequency-modulated bats

The highly specialized CF–FM bats use echolocation calls that consist of a long constant-frequency (CF) component in combination with short initial and terminal FM sequences (compare Figure 5; Neuweiler, G., 1990). The group is typified by horseshoe bats, for instance, *Rhinolophus ferrumequinum* and *Rhinolophus rouxi* (henceforth called *Rhinolophus).* Here also, the relative location of the MSO within the SOC is comparable to the MSO position in other animals (Poljak, S., 1926; Schweizer, H., 1981; Casseday, J. H. *et al.*, 1988). Furthermore, the sheer size of the MSO in *Rhinolophus* indicated its prominent role in central auditory processing. However, the gross anatomy of the nucleus seems somehow modified. There are actually two dorsal and ventral subnuclei (dorsal medial superior olive, DMSO; ventral medial superior olive, VMSO; Casseday, J. H. *et al.*, 1988). Inspired by another CF–FM bat, *Pteronotus parnellii* (the mustached bat; henceforth called *Pteronotus*), some researchers speculated the very large MSO could have partly merged with periolivary nuclei (compare Figure 2; Zook, J. M. and Casseday, J. H., 1982a). Therefore the homology of the MSO and its neighboring periolivary structures in CF–FM bats with those of other mammals has been under debate (Casseday, J. H. *et al.*, 1988; Vater, M. and Feng, A. S., 1990). Histochemical characteristics supported the view that neural subpopulations exist within the MSO of *Pteronotus* (Zook, J. M. and Casseday, J. H., 1982a). Particularly conspicuous was the high GABA immunoreactivity in a small dorsomedial cell population of the MSO, and the apparent lack of a dorsomedial periolivary nucleus (DMPO) in *Pteronotus* (Vater, M., 1995; Winer, J. A. *et al.*, 1995). Both facts fitted the notion of merged nuclei. The principal cell type of the MSO, however, is of bipolar morphology and matched the classical characteristics of MSO cells (Zook, J. M. and Casseday, J. H., 1982a).

3.39.4.2 Input Pattern and Physiology of the Medial Superior Olive in Bats

3.39.4.2.1 Frequency-modulated bats

The input/output pattern of the MSO of *Tadarida*, *Eptesicus*, and *Molossus* fits the view that these animals possess an MSO that is, in principle, just gradually different from the classical MSO. For instance, binaural excitatory inputs to these bats' MSO originate in SBCs of the AVCN, while inhibitory inputs are relayed via the LNTB (from the ipsilateral ear), and the MNTB (from the contralateral ear; Zook, J. M. and DiCaprio, R. A., 1988; Kuwabara, N. and Zook, J. M., 1992; Grothe, B. *et al.*, 1994). Also, as usual, ascending projections from the *Tadarida* MSO mainly target the ipsilateral inferior colliculus (IC; Grothe, B. *et al.*, 1994). But the abundance of binaural neurons that display the classical connectivity of an MSO cell seems gradually reduced in *Tadarida* (whose MSO is changed the least), *Molossus* (representing an intermediate stage), and *Eptesicus* (that displays a substantial shift toward monaurally innervated units; Figure 6). The MSO of all three species exhibits a normal tonotopic arrangement with low frequencies

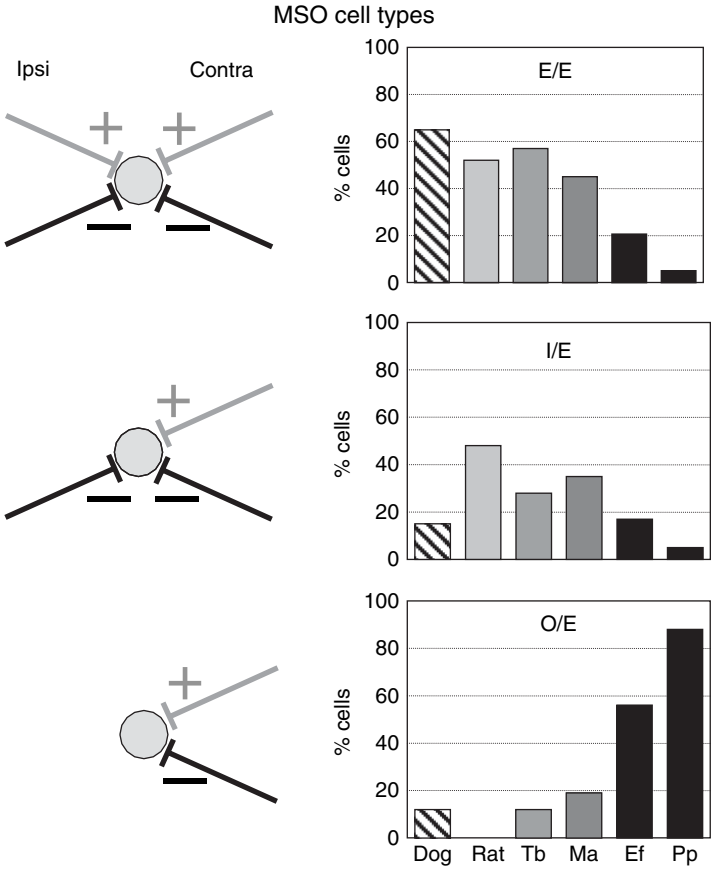

Figure 6 The distribution of projection patterns to MSO neurons in different mammals. The schematic drawings on the left show the main input patterns as suggested by anatomical and physiological studies in several mammals. The right panels show the percentage of the corresponding binaural type as derived from physiological studies. Note that the E/E classification in normal extracellular recordings does not necessarily tell whether there is an additional inhibitory input from the same side. Thus the corresponding pattern in the schematic on the left is the most likely corresponding input pattern, but not inevitably true for all neurons. Note that in all animals including dogs at least one-third of the cells apparently lack ipsilateral excitation. The mustached bat is, even among bats, the most extreme case with almost only monaural cells. Ef, *Eptesicus fuscus* (big brown bat); E, excitatory input; I, inhibitory input; Ma, *Molossus ater* (velvety free-tailed bat); MSO, medial superior olive; O, no input; Pp, *Pteronotus parnellii* (mustached bat); Tb, *Tadarida brasiliensis* (free-tailed bat). Adapted from Grothe, B. 2000. The evolution of temporal processing in the medial superior olive, an auditory brainstem structure. Prog. Neurobiol. 61, 581–610.

being represented dorsally and high frequencies ventrally (Harnischfeger, G. *et al.*, 1985; Grothe, B. *et al.*, 1997).

By the use of sinusoidally amplitude-modulated (SAM) stimuli – to the envelope of which auditory units in the AVCN and MNTB respond in a phase-coupled manner despite high-frequency carrier frequencies – it was shown that bat MSO cells can display rough ITD sensitivity (Grothe, B. *et al.*, 1997; Grothe, B. and Park, T. J., 1998). The sensitivity is likely to be generated by coincident binaural excitation, just as in low-frequency hearing animals (Yin, T. C. and Chan, J. C., 1990). But the observed neural ITD sensitivity was – by far – too broad to be of use for a small-headed animal like *Tadarida*. Its ITD sensitivity has therefore been considered to be epiphenomenal. Still, the rules of computation applied within a significant number of neurons in the MSO circuit of *Tadarida* (which is almost certainly not specialized for ITD processing) could yield usable information on the location of sound sources for animals with large head sizes.

Epiphenomenal coding of binaural disparities aside, most MSO cells of *Tadarida* and *Eptesicus* displayed low-pass filter characteristics to SAM stimuli (Grothe, B. *et al.*, 1997; 2001). A whole range of such neural filters are generated by the interaction of accurately phase-coupled excitatory and inhibitory inputs

that reach the MSO cells with various delays from the SBCs of the AVCN and the principal cells of the MNTB. Notably, it was shown for MSO cells of *Eptesicus* that the characteristic upper cutoff frequency of a neural SAM transfer function might in fact be a byproduct of pause duration filtering (Grothe, B. *et al.*, 2001). Mainly therefore, the putative function of these neurons remains under debate (discussed below; compare also CF–FM bats). In response to high-frequency pure tones, the MSO cells of *Tadarida* and *Eptesicus* predominantly exhibited transient *ON* or *OFF* discharges. These MSO response types matched expectations for interacting sustained excitatory and inhibitory inputs from the AVCN and MNTB, respectively (compare Figure 3; Grothe, B. *et al.*, 1997; 2001).

3.39.4.2.2 Constant-frequency–frequency-modulated bats

In the CF–FM bat *Pteronotus*, the MSO is very large. Just as in other mammals, ascending MSO projections mainly reach the ipsilateral IC (Zook, J. M. and Casseday, J. H., 1982b; Ross, L. S. and Pollak, G. D., 1989). Likewise, as usual, SBCs in the AVCN provide temporally precise excitatory input to the MSO of *Pteronotus*. Also, prominent inhibitory projections to the animal's MSO originate in glycinergic principal MNTB cells, and were actually first described in this animal model (Covey, E. *et al.*, 1991; Kuwabara, N. and Zook, J. M., 1992). At this point, it is helpful to recall that in low-frequency hearing animals these inhibitory projections are involved in tuning the ITD sensitivity of MSO cells (Brand, A. *et al.*, 2002; Grothe, B., 2003). In apparent contradiction, the MSO of *Pteronotus* turned out to be a predominantly monaural structure whose ipsilateral inputs are greatly reduced (compare Figure 6; Covey, E. *et al.*, 1991; Grothe, B. *et al.*, 1992). *Per se*, any substantial contribution to binaural processing was eliminated in the MSO of *Pteronotus*. The neural response of MSO cells is exclusively determined by monaural projections that consist of excitatory inputs from contralateral SBCs, and contralaterally driven inhibitory inputs from principal cells of the ipsilateral MNTB. Both sources display discharges reminiscent of AN activity, and faithfully encode the temporal structure of incoming sounds (Rhode, W. S. *et al.*, 1983; Oertel, D., 1999). Most of their target cells in the *Pteronotus* MSO differ considerably in their response to sound, however, showing transient *ON* and/or *OFF* discharges (Covey, E. *et al.*, 1991). An *in vivo* application of the glycine antagonist strychnine that reversibly blocks inhibitory inputs from the MNTB results in primary-like MSO responses (Grothe, B. *et al.*, 1992; Grothe, B., 1994). Hence, transient responses are generated by interacting excitatory and inhibitory projections. Such MSO characteristics could be used by the bats to encode sound onsets and offsets, respectively. But the implications for the function of the MSO reach beyond the generation of transient responses. By a systematic variation of the delay between excitatory and inhibitory projections, the animals could generate a bank of specific neural filters for the temporal envelope structure of sounds in the monaural MSO (Figure 7). Single-unit response properties to SAM sounds exemplified these neural filters *in vivo* (Grothe, B., 1994). Respective findings suggested that MSO neurons phase-lock to SAM rates up to 1000 Hz whenever inhibitory inputs are experimentally neutralized. Controls revealed that, naturally, MSO neurons exhibit low-pass filter functions in response to SAM stimuli (Figure 8). These filter functions are perfectly matched to amplitude and frequency-modulation rates imprinted onto the echo signals received by *Pteronotus* while preying on fluttering insects (compare Figure 5; Henson, O. W. *et al.*, 1987).

3.39.4.3 Function of the Medial Superior Olive in Bats

3.39.4.3.1 Constant-frequency–frequency-modulated bats

As mentioned above, fluttering prey objects within the emitted acoustic beam of echolocation calls do reflect echoes that are FM and amplitude modulated (AM) (Henson, O. W. *et al.*, 1987). This repetitive modulation is captured by the long-lasting CF component of the echo, and allows the detection of wing-beating insects even in dense foliage (i.e., the CF–FM bats' predominant foraging range) that creates a cluttered echo environment. Therefore, *Pteronotus*' preying strategy relies heavily on temporal pattern recognition within the CNS, and the *Pteronotus* MSO seems optimized to serve this task. To enhance the precision of temporal information, an elimination of binaural inputs to the *Pteronotus* MSO appears as a straightforward adaptation. Otherwise, the temporal analysis of an echo structure could suffer from position-dependent binaural parameters. In fact, both ITDs and ILDs affect sound-envelope coding in binaural brainstem neurons (Joris, P. X. and Yin, T. C., 1995; Grothe, B. *et al.*, 1997). In the FM bat *Tadarida* that possesses a largely binaural MSO (discussed below), ILD effects on neural SAM transfer functions were found to be significant, and rather unpredictable. Notably, temporal precision is also vital to aid

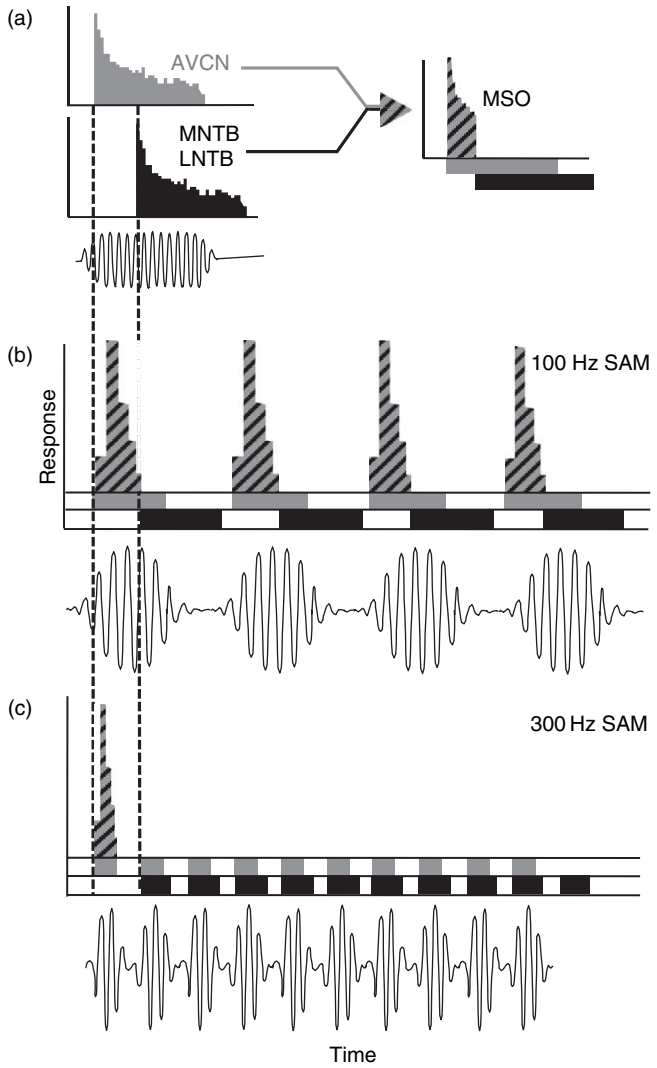

Figure 7 Schematic drawing of the monaural interaction of excitation from the AVCN (gray) and inhibition from the MNTB (black) as first described for the MSO in *Pteronotus parnellii.* (a) Pure tone stimulation leads to primary-like activity in the excitatory AVCN and the inhibitory MNTB. In most MSO neurons the inhibition is delayed by a fixed amount (-3 to $+5$ ms), leaving a small window where the cell can respond to the excitatory input before it is completely inhibited by the MNTB. The result is a phasic ON response except in a minority of cells where the inhibition arrives simultaneously or even earlier. These neurons are inhibited throughout the stimulus duration but respond with a rebound OFF. (b) The same temporal interaction of excitation and delayed inhibition will cause a phase-locked response to the envelope of SAM tones, as long as the modulation frequency is low. (c) Because of the fixed delay, the inhibition will start to overlap with the excitation in response to the following subsequent cycle when the modulation frequency reaches a certain limit (the limit depends on the actual delay of inhibition). The response to all cycles except the first would start to decrease at this modulation frequency and completely stop at even higher rates. A slightly slower time course of the inhibition (little longer duration) and some temporal summation would prevent the cell from recovering at much higher rates. AVCN, anteroventral cochlear nucleus; MNTB, medial nucleus of the trapezoid body; MSO, medial superior olive; SAM, sinusoidally amplitude modulated. Adapted from Grothe, B. 1994. Interaction of excitation and inhibition in processing of pure tone and amplitude-modulated stimuli in the medial superior olive of the mustached bat. J. Neurophysiol. 71, 706–721.

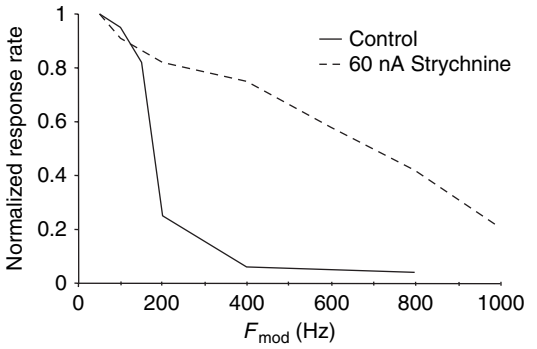

Figure 8 Normalized response rates of an MSO neuron to SAM stimuli with different modulation frequencies (modulation transfer function). The abscissa gives the modulation frequency, the ordinate the normalized response. Under control conditions the neuron responds only to modulation frequencies below 200 Hz. In the presence of strychnine, however, the neuron responds to much higher modulation frequencies. Using the 50% level as a criterion, the cutoff frequency shifts from about 180 (control) to above 700 Hz when glycinergic inhibition is blocked. MSO, medial superior olive; SAM, sinusoidally amplitude modulated. Adapted from Grothe, B. 2000. The evolution of temporal processing in the medial superior olive, an auditory brainstem structure. Prog. Neurobiol. 61, 581–610.

the distance estimation between target and bat that is calculated from the delay between the FM terminal sequence of a CF–FM call and its echo (Neuweiler, G., 1990). In this context, temporally precise *ON* and *OFF* responses to acoustic stimuli that were observed in the *Pteronotus* MSO might contribute to capture the timing of call emission and incoming echo with high acuity.

3.39.4.3.2 Frequency-modulated bats

Apart from *Pteronotus*, the putative MSO function was best studied in three bat species that exclusively use FM echolocation calls. Hence, *Tadarida*, *Molossus*, and *Eptesicus* represent species that might not be as specialized for temporal pattern recognition as *Pteronotus*. This is corroborated by the fact that all three species use less cluttered environments for foraging, meaning their potential prey objects appear more prominent in echo signals (Neuweiler, G., 1990). Nonetheless, when compared to *Pteronotus*, very similar SAM coding properties were unraveled in the MSO of *Tadarida* and *Eptesicus* (Grothe, B. *et al.*, 1997; 2001). A fundamental difference concerns the binaurality of the MSO, however, that is maintained to various degrees in *Tadarida*, *Molossus*, and *Eptesicus* (Harnischfeger, G. *et al.*, 1985; Zook, J. M. and DiCaprio, R. A., 1988; Kuwabara, N. and Zook, J. M., 1992; Grothe, B. *et al.*, 1994), but is largely reduced in *Pteronotus* (Covey, E. *et al.*, 1991). In bats that preferentially prey in open spaces rather than in dense foliage, like *Tadarida* and *Molossus*, the distribution of binaurally excited neurons in the MSO nearly matches the picture drawn for the dog and the cat MSO (Goldberg, J. M. and Brown, P. B., 1969; Yin, T. C. and Chan, J. C., 1990). The fidelity of temporal pattern analysis in *Tadarida* therefore suffers from the impact of interaural disparities on the timing of MSO inputs (Grothe, B. *et al.*, 1997). As a trade-off, binaural information is made available to integrate spatial and temporal information (Grothe, B. and Neuweiler, G., 2000). Hence, SAM filtering observed in the MSO of *Tadarida* might not reflect a pure wing beat pattern filter like in *Pteronotus*, and could merely represent a by-product of processing other temporal information. Strong indications for the MSO's role in pause duration tuning, and speculations on its part in sound duration tuning, were fuelled by a study on *Eptesicus* that demonstrated that interpulse intervals (and not modulation rates) were crucial for the sound envelope filter properties of MSO neurons (Grothe, B. *et al.*, 2001). In *Eptesicus*, the MSO input pattern rather represents a stage in between the extreme MSO variants that are embodied by *Tadarida* and *Pteronotus* (and that were linked to their individual echolocation strategies in open spaces and dense foliage, respectively). Interestingly, the intermediate anatomical status of the MSO in *Eptesicus* correlates to the variability of its species-specific echolocation calls and foraging ranges (in open and cluttered environments). During subsequent phases of its approach on flying prey, *Eptesicus* initially employs pseudo-CF echolocation calls (Simmons, J. A. and Stein, R. A., 1980) that could serve pattern-based prey recognition much like in *Pteronotus*. As the approach on prey continues, however, emitted calls of *Eptesicus* become steeply FM, and might rather serve spatial resolution in terms of distance. Pause duration tuning could assist this task, and might be supported by the typical transient ON and OFF responses in the *Eptesicus* MSO.

Taken together, the gradual variation of inputs to MSO cell populations of different bat species seems related to their habitat, and foraging strategy. Both exert pressure to process specific features of echo envelope or frequency patterns, and might enforce a physiological adjustment of MSO processing rules. Anatomical data and neural responses in

bats suggest that adjustment could be accomplished by regulating the flow of feed-forward information into the MSO.

3.39.5 Conclusions

Research on the bat MSO has taught us that gradual modifications of the MSO input could result in different ways of analyzing the temporal structure of sounds, related to behavioral strategies and habitats. In extension of the gerbil animal model (where it has been demonstrated that inhibitory projections to the MSO undergo experience-driven refinement), in bats also excitatory inputs were heavily adapted in accord with evolutionary pressures. It should be noted that MSO neurons emerge very early during ontogenesis, and thus the ancient MSO circuit is likely to represent a primitive neural configuration (Kudo, M. *et al.*, 2000). This circuit might still be little modified in some modern mammals whose hearing periphery hardly changed since the onset of hearing of airborne sound (Gregory, W. K., 1929; Rosowski, J. J., 1992; Frost, S. B. and Masterson, R. B., 1994; Mills, D. M. and Shepherd, R. K., 2001). In other mammals, some of which were reviewed here, extreme changes of the auditory system have been wrought by evolution (Grothe, B. *et al.*, 2004). As new habitats were conquered, new auditory cues became dominant and possibly vital to these developing species. The MSO has been maintained as a structure in all mammals investigated so far, and it ultimately reflects the auditory world an animal lives in by its gross anatomy, input pattern, and fine structure (Figure 9; compare also Figures 1, 2, and 6). The nucleus therefore serves well to unravel the microevolution and macroevolution of a neural circuit in the context of well-defined sensory parameters.

The distribution of MSO input patterns in bats, as well as other high- and low-frequency hearing mammals, is reconciled by an expanded concept of an ancient MSO: the text book unit of the MSO features four inputs, that is, combined inhibitory and excitatory projections from each ear. During the species-specific ontogenesis of the auditory brainstem, the initial anlage of four predominant inputs might be adjusted by axon pruning and synaptic elimination, while functional connections are facilitated (e.g., Sanes, D. H. and Friauf, E., 2000; Kapfer, C. *et al.*, 2002). In the gerbil MSO, innervation patterns were shown to undergo a combination of experience-driven and autonomous refinement processes that shift, or eliminate, the input weight of synaptic connections (Kandler, K., 2004). It remains open how developmental plasticity might be stabilized during evolution to permanently establish connectional changes that became primarily independent of sensory experience. Our scenario, however, suggests that MSO nuclei of different species might essentially encompass primordial cells at different stages of structural and functional refinement.

A monaural MSO, as it is found in *Pteronotus*, seems well adapted to pattern processing, a feature that is of great import for the foraging success of *Pteronotus* within its densely cluttered habitat. Its MSO's ability for envelope filtering in a behaviorally relevant range is based on the precise timing of tightly coupled excitation and inhibition from the contralateral ear (Covey, E. *et al.*, 1991). Reminiscent neural filters (often described as SAM filters) are also present in bats that possess a binaural MSO (Grothe, B. *et al.*, 1997; 2001). Similar response properties are maintained even in low-frequency hearing ITD-users (Behrend, O. *et al.*, 2000). The general occurrence of SAM filter units in the MSO of a number of widely unrelated species suggests that – with the possible exception of CF–FM bats – these units represent a by-product of the processing of other temporal aspects of complex sounds, for instance, of pause duration coding (Grothe, B. *et al.*, 2001). Yet the principal potential of the MSO circuit for temporal sound pattern processing shows across the range of species investigated.

The binaural MSO was linked to ITD processing by coincidence detection in low-frequency hearing mammals (Goldberg, J. M. and Brown, P. B., 1969; Yin, T. C. and Chan, J. C., 1990), and again the relative timing of the contralateral excitatory and inhibitory input has been proven to be vital – in this case to shape the ITD sensitivity within behaviorally relevant ranges (Brand, A. *et al.*, 2002). Remarkably too, the epiphenomenal ITD sensitivity of the binaural MSO of high-frequency hearing bats had established that the MSO's rules of processing promote binaural coincidence detection without any specialization for ITD coding. One might conclude that a still largely ancient MSO, as it became apparent by anatomical and physiological studies in *Tadarida*, indeed also shows a preadaptation for ITD coding.

Across the reviewed species, the MSO exemplifies that individual inputs, like the fast and precise inhibition from the contralateral MNTB, can be designated to species-specific processing

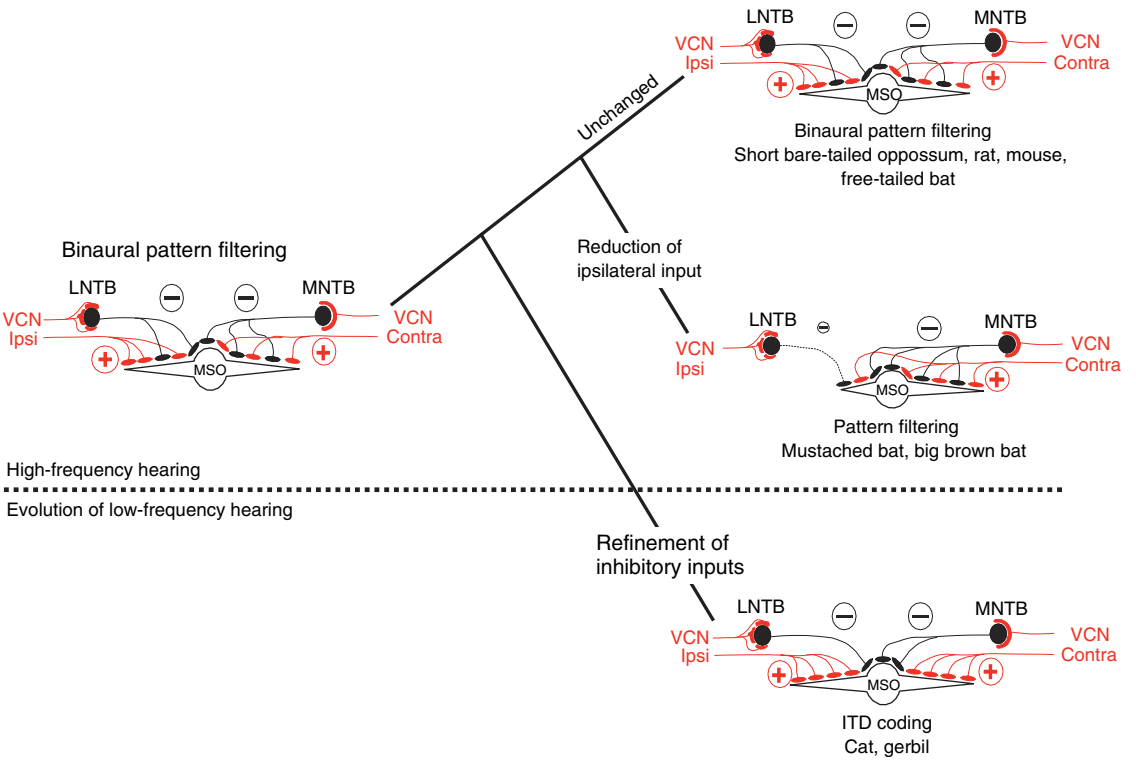

Figure 9 A scenario for the evolution of the MSO. The ancestral precursor is assumed as similar to the free-tailed bat MSO in that it showed specializations neither for pure pattern processing nor for ITD processing. This kind of MSO would have shown pattern filtering (e.g., amplitude modulation filtering). The filter characteristics were, however, influenced by binaural cues and, hence, by the position of a sound source. This MSO might be rather unchanged in most mammals that do not show any adaptations for low-frequency hearing. Some bats (like the mustached bat and partly the big brown bat) reduced the ipsilateral inputs to the MSO and, thereby, turned it into a pure pattern filter. A different direction took the evolution of the MSO in low-frequency hearing animals. Because of the preadaptation for ITD coding it has been used as the primary site for localizing low-frequency sounds in the horizontal plane. Several specializations occurred in order to improve the ITD sensitivity. One might have been a change in the inhibitory inputs by refining them to the cell somata. ITD, interaural time difference; LNTB, lateral nucleus of the trapezoid body; MNTB, medial nucleus of the trapezoid body; MSO, medial superior olive; VCN, ventral cochlear nucleus. Adapted from Grothe, B. 2000. The evolution of temporal processing in the medial superior olive, an auditory brainstem structure. Prog. Neurobiol. 61, 581–610.

demands. That is, inhibition of the MSO is likely to serve pattern recognition and spatio-temporal integration of high-frequency acoustic signals in bats – while, conversely, it supports the spatial resolution of low-frequency sound sources in gerbils. However, the epiphenomenal ITD and/or SAM sensitivity that can be observed in the MSO regardless of a species' auditory specialization suggests that the principal rules of MSO processing stay rather uniform across mammals. Only, the basic neural algorithm can be finely adjusted – by the regulation of feed-forward information (bats; Covey, E. *et al.*, 1991) and membrane properties (guinea pigs, gerbils; Smith, P. H., 1995; Magnusson, A. K. *et al.*, 2005).

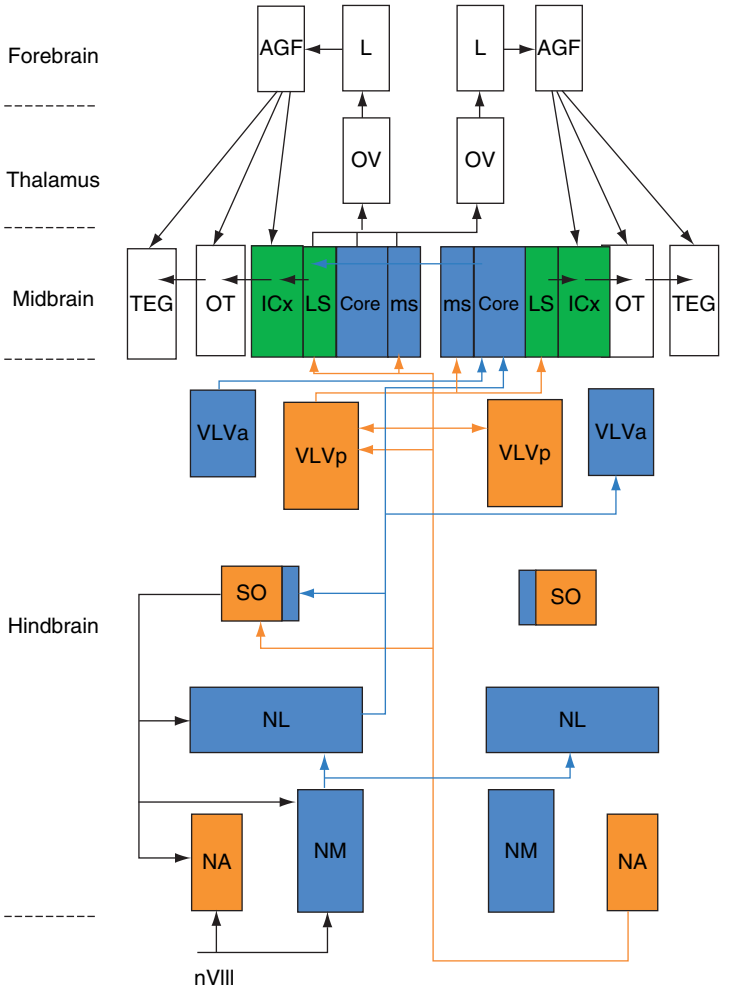
3.40.1 Acoustic Cues for Sound Localization

Experiments show that the barn owl uses the interaural time difference (ITD) for determining sound azimuth and the interaural intensity difference (IID) for elevation (Moiseff, A. and Konishi, M., 1981). The ITD varies systematically as a function of sound azimuth. The maximal ITD experienced by the owl is about 170 μs and the minimal ITD is zero when sound emanates from a place equidistant to the two ears. IID is due to both the head's shadow in the sound field and the directional sensitivity of the external ears in mammals. Owls do not have any external ear, but the feather ruff that surrounds their face serves as a sound-collecting device. The facial ruff consists of left and right halves that are separated by a tall ridge of feathers along the midline of the face. In barn owls, the left ear opening is located higher in the ruff than the right one. This asymmetry and other differences between the left and right halves of the ruff make the left and right ears more sensitive to sound coming from below and above eye level, respectively. This difference in the ear's directional sensitivity causes IID to vary as a function of sound elevation. In owl species with symmetrical ears, IID does not change along the vertical plane. Given a constant size of the head and sound collectors, shorter wavelengths and thus higher frequencies produce greater intensity differences than lower frequencies. The barn owl needs relatively high frequencies (5–8 kHz) for accurate localization in elevation. Thus, to localize sound in two dimensions, the owl must be able to derive both interaural cues from the same high-frequency signal. Mammals including humans, which use both cues for azimuth, detect ITD only in low-frequency ranges and IID in high-frequency ranges (Macpherson, E. A. and Middlebrooks, J. C., 2002).

3.40.2 Parallel Pathways for Processing Interaural Time Difference and Interaural Intensity Difference

The owl's auditory system processes the two cues in two separate pathways. The owl's ear performs spectral analysis of complex sound and encodes the phase and amplitude of each frequency component. Auditory neurons phase-lock by firing at or near a particular phase of tonal stimuli. In barn owls, phase-locking occurs even in auditory neurons that are tuned to high frequencies such as 9 kHz (Köppl, C., 1997). Phase-locking is the basis for the detection of interaural phase differences from which ITDs are derived. The rate of discharge of auditory fibers encodes intensity, because it varies as a function of stimulus intensity. Birds have two anatomically separate cochlear nuclei on each side, nucleus angularis and nucleus magnocellularis, and each primary auditory fiber divides into two collaterals, one innervating nucleus angularis and the other nucleus magnocellularis. Neurons of nucleus magnocellularis phase-lock to tonal stimuli, whereas those of nucleus angularis generally do not. Thus, each cochlear nucleus is more specialized to process one cue than



ITD and ILD are processed by parallel pathways

Figure 1 Parallel auditory pathways. The owl's brainstem auditory system consists of two parallel pathways. The blue areas indicate the nuclei of the time processing pathway and the brown areas the nuclei of the intensity processing pathway. The areas where neurons respond to both ITD and IID are indicated by green. The thick and thin arrows indicate anterograde connections, respectively, in the time and intensity pathways. The dashed lines with arrowheads on both ends represent reciprocal connections. The connections are symmetrical in two sides of the brainstem, but only one side is shown for simplicity. the other cue (Sullivan, W. E. and Konishi, M., 1984; Takahashi, T. *et al.*, 1984). The two pathways that start from the cochlear nuclei are anatomically separate until they converge in the inferior colliculus (Takahashi, T. and Konishi, M., 1988a; 1988b). The two channels are referred to as the time and intensity pathways (Figure 1).

3.40.3 Detection and Coding of Interaural Time Difference

Nucleus magnocellularis projects bilaterally to a third-order station, nucleus laminaris, which is presumably the avian homolog of the superior medial olivary nucleus of mammals. Thus, nucleus laminaris

is the first site of binaural convergence in the time pathway. Magnocellular and laminaris neurons form circuits for detection of ITDs by a method similar to that originally proposed by Jeffress L. A. (1948). Laminaris neurons serve as coincidence detectors which fire maximally when impulses arrive simultaneously from the left and right magnocellular nuclei. Axons of magnocellular cells convey phase-locked impulses to an array of laminaris cells with delays. These delays augment in the opposite direction for the ipsilateral and contralateral inputs, because the length of axonal paths for the two sides increases toward the opposite ends of the array (Carr, C. E. and Konishi, M., 1990). When impulses travel to a laminaris cell by a longer path on one side than on the other side, they reach the cell at different times. In general, a left–right difference in impulse arrival time (T_a) consists of an ITD in the stimulus and a difference in impulse conduction delays (T_c). Hence, $T_a = \mathrm{ITD} + T_c$. Coincidence means $T_a = 0$, which obtains when $-\mathrm{ITD} = T_c$; that is, ITD equal to T_c in magnitude but opposite in sign. Because the length of axonal paths varies systematically in both left and right inputs, T_c should also vary regularly. This argument means that neurons sensitive to different ITDs should be systematically arranged in nucleus laminaris (Peña, J. L. *et al.*, 2001).

Laminaris neurons are, however, not all or nothing coincidence detectors, for their responses decrease gradually from maximum to minimum as stimulus timing changes from perfect coincidence to out of phase by 180°. They also respond to monaural stimuli. Laminaris neurons respond best to a single interaural time difference (ITDi) which is independent of frequency. But they respond also optimally to other ITDs which vary with frequency. The relationship between these ITDs and ITDi is $\mathrm{ITDi} \pm nT$, where T is the period of the stimulus tone and n is an integer. This phenomenon, called phase ambiguity, is due to the use of phase-locked impulses for the measurement of ITD. Laminaris neurons fire maximally when they receive binaurally synchronous trains of phase-locked impulses. The coincidence of the two trains recurs every time ITD is changed by an integer multiple of the period of the stimulus tone, causing the laminaris neurons to discharge maximally. Nucleus laminaris projects both to the core of the central nucleus of the inferior colliculus (ICc) and to one of the lemniscal nuclei (VLVa). The core projects to the contralateral lateral shell of the central nucleus of the inferior colliculus (ICcl).

3.40.4 Processing of Interaural Intensity Differences

The nucleus angularis, the first station in the intensity processing pathway, projects to a lemniscal nucleus called the VLVp in which neurons are excited by sound in the contralateral ear and inhibited by sound in the ipsilateral ear. The excitatory input comes from the contralateral nucleus angularis and the inhibitory input from the other VLVp.

The louder the sound in the contralateral ear is, the greater is the response, whereas the louder the sound in the ipsilateral ear is, the greater is the degree of inhibition. Thus, the response of a VLVp neuron varies as a function of the difference in sound intensity between the two sides, even though the neuron still responds to monaural stimulation of the contralateral ear alone. Furthermore, the threshold and degree of inhibition changes systematically from the dorsal to ventral direction of VLVp (Manley, G. A. *et al.* 1988; Mogdans, J. and Knudsen, E. I., 1994). This gradient suggests a map of IIDs in this nucleus.

3.40.5 Convergence of Time and Intensity Pathways in the Midbrain

VLVp neurons project to the lateral shell of the central nucleus of the ICcl. ICcl neurons respond to narrow ranges of frequency and also to combinations of ITD and IID, indicating that the time and intensity pathways converge in each frequency band. The ICcl projects to the adjoining area called the external nucleus of the inferior colliculus (ICx) where neurons respond to broad frequency ranges (3–9 kHz). When the stimulus is a broadband signal, ICx neurons do not respond to ITD or IID alone but require specific combinations of the two cues and unfavorable combinations induce inhibition. Recent studies show that ICx neurons multiply postsynaptic potentials from the two pathways to create the combination sensitivity (Peña, J. L. and Konishi, M., 2001).

3.40.6 A Map of Auditory Space

The tuning of ICx neurons to specific pairs of ITD and IID makes these cells selective for the direction of sound propagation, because such combinations obtain only when sound comes from particular areas in an owl's auditory space. These areas are

called receptive fields and cells having such areas are called space-specific neurons. ICx neurons are systematically arranged according to the location of their receptive fields, thus forming a neural map of auditory space. The topographical representation of auditory space is due not to anatomical projections of the inner ear like the retinotopic map of the visual field but to central synthetic processes. Nevertheless, the auditory space map projects onto the retinotopic map of the optic tectum. The tectal neurons making up the bimodal map respond to both auditory and visual stimuli coming from the same area in space, that is, their auditory and visual receptive fields are mutually aligned (Knudsen, E. I., 1982). Similar maps are found in the superior colliculus of the ferret, although the mechanisms underlying these maps appear to differ from those in owls (King, J. A. and Carlile, S., 1995).

Owl species with symmetrical ears also have space-specific neurons in their ICx, but these cells map only azimuth, because their receptive fields do not have elevational boundaries, although the cells are tuned to combinations of ITD and IID (Volman, S. F. and Konishi, M., 1990). In these owls, IID does not change as a function of sound elevation, because the highest frequency audible to them is too low for this change to occur.

3.40.7 A Motor Map for Sound Localization

The overt behavior that characterizes sound localization in owls is rapid head rotation. The bimodal map of space in the optic tectum projects to a motor map for gaze control which is found in the optic lobe. Neurons of the motor map innervate the medullary nucleus involved in the control of head rotation. The tectal motor map encodes the direction, speed, and amplitude of head rotations (du Lac, S. and Knudsen, E. I., 1990). Experiments reveal that the map contains separate circuits for head rotations in azimuth and elevation (Masino, T. and Knudsen, E. I., 1990).

Both the inferior colliculus and the optic tectum are in the midbrain. Is the forebrain involved in sound localization? Lesions of the optic tectum impair sound localization, but the owl can still localize sound (Wagner, H., 1993). Ablations of both the optic tectum and the nucleus ovoidalis, the avian homolog of the medial geniculate body, completely abolish the ability of owls to localize sound (Knudsen, E. I. *et al.*, 1993). The nucleus ovoidalis receives inputs from all parts of the inferior colliculus except the ICx. Many ovoidalis neurons are tuned to combinations of ITD and IID. Nucleus ovoidalis projects to the forebrain auditory area field L which, in turn, projects to the archistriatum. This structure contains many neurons tuned to combinations of ITD and IID. But neither field L nor archistriatal neurons form an auditory space map. Focal electrical stimulation of the archistriatum induces head rotations even when the tectal motor map is disabled. Interestingly, lesions of the archistriatum cause the owl turn its head toward sound sources like an automaton. Barn owls determine and memorize sound locations before orienting toward them. When the archistriatum of a barn owl is inactivated with muscimol, the owl can no longer remember the computed sound location, even though he can still localize the sound source if it continues to emit the signal (Knudsen, E. I. and Knudsen, P. F., 1996). Thus, one of the functions of the owl's archistriatum may be storage of working memory.

Glossary

chordotonal organ Sensory organ found in insects and crustaceans. The name means thin structure, associated with hearing.

diffraction A collection of physical phenomena associated with wave propagation, such as the bending, spreading, and interference of waves passing by an object or an aperture that disrupt the propagation of the wave.

scolopale cell Cell that mechanically supports the geometry of a scolopidium, including the mechanosensory neurones. The scolopale cell contains rod-like structures (presumably actin) that confer mechanical rigidity and stability.

scolopidium (plural: scolopidia) Multicellular ensemble comprising one or more mechanosensory neurons, a scolopale cell, and several accessory support cells. A scolopidium is the fundamental unit of mechanoreception in insects and crustaceans.

3.41.1 Introduction

Like any of their other senses, hearing in insects is a superbly adapted and sophisticated process. In fact there is more to insect hearing than meets the eye; insect ears may be anatomically simpler and smaller than those of other animals, yet they detect and process airborne sounds with just as much accuracy and sensitivity (Robert, D. and Göpfert, M. C., 2002). While, admittedly, there are major differences in the mechanisms employed in detecting and processing sounds, some remarkable functional and structural similarities have been unveiled at the cellular and molecular levels (Eberl, D. F., 1999; Eberl, D. F. *et al.*, 2000). The process of hearing in insect is commensurate with the evolutionary diversity, ubiquity, and versatility of the class Insecta (Robert, D. and Hoy, R. R., 1998). Adapted – and adapting – to live in a multitude of habitats and move often swiftly between them, insects have rich and diverse sensory ecologies. Displaying an astonishing morphological diversity, ears have been found on almost any segment of the insect body (Fullard, J. H. and Yack, J. E., 1986; Robert, D. and Hoy, R. R., 1998). Any one auditory insect species has evolved a pair of bilateral, specialized hearing organs on one segment, with the notable exception of bladder grasshoppers which are endowed with a series of abdominal sound sensors (van Staaden, M. J. and Römer, H., 1998). It has been very astutely suggested (Meier, T. and Reichert, H., 1990; Yack, J. E. and Fullard, J. H., 1993; Yager, D. D., 1999) that such versatility in developing an ear is based on the prior presence of

the somatosensory chordotonal system distributed all over the insect's body. The mechanosensory multicellular units in that system, the scolopidia, comprising one or more ciliated neurons and accessory cells, are remarkably similar to those used in hearing organs (Field, L. H. and Matheson, T., 1998; Yack, J. E., 2004). Seemingly extreme evolutionary specialization in some insect auditory systems stands out in their functional organization.

Operationally, the process of hearing essentially amounts to detecting the amplitude, the frequency, and the timing of an incident sound wave (Lord Rayleigh, 1876). Detecting adequately each of these three acoustic physical parameters requires specific qualities of the mechanical and neuronal structures of an ear (Robert, D. and Göpfert, M. C., 2002; Hennig, M. *et al.*, 2004; Yack, J. E., 2004). The constraints imposed to fulfill these tasks are not trivial, sometimes they work against each other, and are still matter of much research. For example, the mechanical characteristics allowing auditory sensitivity, such as resonance, generally come to a cost in the temporal resolution of the system. But can an auditory system perform well at both tasks? The functional compromises and the novel mechanisms implemented to detect sound amplitude, frequency, and timing are at the heart of fundamentally understanding the process of hearing. To put it abruptly, no insect ear is good at everything, but some exhibit innovative specializations that excel at one task. The ears of auditory specialists are particularly enriching to comparative research, providing unique insights into evolutionary adaptations to common problems of acoustic detection. One such insect specialist is the fly *Ormia ochracea* and her prosternal hearing organs specialized for directional hearing.

This chapter will focus on some of the mechanisms employed by insects for sound localization. Because they are important in understanding the particularities of insect hearing, the physical constraints will be presented, using a few selected cases to illustrate how the necessity of small size fostered sensory innovation.

3.41.2 Constraints and Limitations

Like most animals, insects are endowed with bilateral symmetry. This symmetry results in the positioning of the ears on each side of the body. There are some notable exceptions, like that of the praying mantises for which the ears are still paired but are located medially, in a ventral thoracic cleft (Yager, D. D. and Hoy, R. R., 1986), or that of the tachinid parasitoid fly *Ormia*, where the ears are near the midline and are linked across it (Robert, D. *et al.*, 1996).

The diminutive size of insects together with the physical laws of sound propagation constitute a set of acute problems for the directional detection of impinging sounds. Numerous studies of acoustic communication and hearing have also shown that insects are small compared not only to other auditory animals, but also to the wavelength of the sounds that are biologically relevant (Michelsen, A., 1998; Robert, D. and Hoy, R. R., 1998). Fundamentally, symmetrically bilateral auditory receivers and their relative position on the animal's body constitute starting conditions that constrain the process of directional hearing. The fundamental problem is rather simple and has been recognized long ago (Lord Rayleigh 1876; Autrum, H., 1940). The smaller the animal, the lesser the auditory cues available for the directional detection of sound. One of the two key physical parameters used to detect the direction of an incident sound wave is the time difference in the arrival of the sound at each ears or, for continuous sounds, the difference in phase between the two auditory signals. In insects, the ears are set so close together that this temporal cue, the interaural time difference (ITD), is extremely small, also by human standard. If the distance between the ears, the interaural distance (ID), is half a millimeter, the maximum ITD is in the order of 1 μs (Robert, D. *et al.*, 1996). This is a short time for any nervous system, not only for that of a small insect (de Ruyter van Steveninck, R. R. *et al.*, 1997). Another constraint is associated with small size: the lack of diffractive conditions. In other, larger animals the size (and density) of the tissue supporting the hearing organs is large compared to the wavelength of sound resulting in diffractive interactions with impinging sounds. Diffraction results in sound pressure to vary in space, whereby, generally, the side of the diffractive structure facing the sound source experiences an increase while the other side experiences a decrease in sound pressure. The difference in sound pressure between the ears constitutes the second key cue for directional sound detection, the interaural intensity difference (IID). Very little or immeasurable diffraction, however, takes place for objects that are *c.* 10 times smaller than the wave length of incident sound waves (Morse, P. M. and Ingard, K. U., 1968, Michelsen, A., 1992; 1996, Robert, D. *et al.*, 1999). It is worth noting that some of the better known and larger ears, those of locusts and cicadas, have

tympanal membranes spanning only about 2–3 mm in diameter. Apparently, the difficulties associated with large wave length and small body sizes are also experienced by fish and their remarkable auditory diversity (Fritzsch, B., 1999).

For insects with subcentimeter body sizes frequencies lower than *c.* 7 kHz do not generate sufficient diffraction to yield measurable IIDs. In such cases, ITDs become the principal cue for directional information. For completeness, there is a third acoustic cue used by animals: the change in the spectral composition of the incident sound wave due to direction-dependent diffraction (Middlebrooks, J. C. and Green, D. M., 1991; Wightman, F. L. and Kistler, D. J., 1997). As shown above, diffraction can be limited for insects, resulting again in small, but existing, spectral variations. The capacity of insects to perform a frequency analysis – with the resolution required to detect diffraction-based spectral variations – is still not known. Frequency analysis has been documented in several insect species (Pollack, G. S., 1998; Fonseca, P. J. *et al.*, 2000). It thus becomes apparent that the constraints are multiple; to generate sufficient diffractive IIDs, insects should use higher frequencies for their acoustic communication, but this would signify a much reduced distance of propagation and reduced localization accuracy due to complex propagation paths in the usual cluttered environment (Bennet-Clark, H. C., 1998). Conversely, lower frequencies facilitate long distance propagation, but are inefficiently produced by small sound-producing structures – oscillating wings, legs, or tymbal organs – and are notoriously difficult to localize (Bennet-Clark, H. C., 1998; Michelsen, A., 1998).

Buffeted between the physics of sound propagation and small body size, how do small insects detect the direction of a sound wave?

3.41.3 Sounds, Ears, and Directionality

Insect ears can be either tympanal or flagellar (antennal). Both types are highly sensitive to airborne acoustic energy and as such are qualified as hearing organs (Tautz, J., 1977). The basic differences between these two auditory anatomies will be presented here, as they pertain to the way directional information is gathered from different physical components of the propagating sound wave. Whilst tympanal ears are sensitive to the pressure (a scalar quantity), flagellar ears are sensitive to particle velocity (a vectorial quantity). The pressure component of a sound wave propagates far from the sound source, the so-called far-field, while particle velocity dominates the overall sound energy very near to the sound source, in the near-field. Flagellar ears have thus been called near-field receivers to reflect their sensitivity to particle velocity.

3.41.3.1 Directional Detection with Particle Velocity Receivers

The capacity of insects to hear with their antennae has long been suggested (for instance in mosquitoes, Johnston, C., 1855). The directionality of the mosquito antennal ears has also been investigated (notably by Belton, P., 1974). Other forms of particle velocity receivers have been reported such as, among others, the filiform hairs borne on the body wall of caterpillars (Tautz, J., 1977), the cercal hairs of crickets (Gnatzy, W. and Tautz, J., 1980; Shimozawa, T. and Kanou, M., 1984). Particle velocity receivers are directional, a capacity due to two independent facts. First, because the physical quantity they respond to – particle velocity – is vectorial (unlike the scalar pressure component), such receivers are inherently directional. The bulk oscillations of the air particles take place in the direction of sound propagation and drive the antenna or hair in the same direction by viscous coupling (Fletcher, N. H., 1978). Thus, directional information is directly sensed by the sound-receiving structure. In the vicinity of complicated sound radiators, such as a pair of beating wings, the exact patterns of velocity vectors and how they contribute to directionality remain unknown. Second, the anatomy and mechanical responses of hair-like structures and antennae condition directionality. Any asymmetry in the flagellar structure (curvature of shaft, asymmetrical hair cover, or articulation at the base of the shaft) may alter the mobility of the entire structure. This may result in a directional sensitivity of the system oscillating in the sound field. Acting as near-field receivers, some of the filiform hairs borne on the cuticle of the caterpillar of a noctuid moth have been shown to have an inherent directional response to sound that is related to hair curvature (Tautz, J., 1977). The capacity of flagellar auditory structures to directionally respond to sound has been investigated (Belton, P., 1974), but how directional information is encoded at the neural level has not received much attention recently. An outstanding question for mosquitoes pertains to the angular

resolution of directional sensing, at the mechanical, neural, and behavioral levels. Also, because hearing is an active process in mosquitoes (Göpfert, M. C. and Robert, D., 2001; Jackson, J. C. and Robert, D., 2006), the possible role of motile sensory neurones in directional hearing is yet to be addressed.

3.41.3.2 Tympanal Ears as Creative Variations on One Theme

The morphology of tympanal ears varies greatly across insect species, yet the general construction responds to the necessity of capturing the energy conveyed in a field of acoustic pressure (Hoy, R. R. and Robert, D., 1996; Michelsen, A., 1998). Receiving acoustic pressure, for example, converting acoustic energy into mechanical motion, is done by a thin cuticular membrane backed with an air-filled cavity. The mechanical response is then sensed by mechanosensory scolopidial cells generally grouped in a chordotonal organ (Field, L. H. and Matheson, T., 1998; Yack, J. E., 2004). Sensing the direction of a sound wave is one of the essential tasks of audition and, as we shall see, insects have evolved quite original solutions to that particular problem (Michelsen, A., 1998; Robert, D. and Hoy, R. R., 1998).

3.41.3.3 Directional Sound Detection Using Tympanal Ears

For insects, the main acoustic cues for directional hearing are ITDs and IIDs.

The cues are mainly determined by the spatial separation between the ears, the ID, and their position relative to the sound source. ID can be as short as a few millimeters for crickets, grasshoppers, moths, cicadas. The shortest distance reported thus far is that of parasitoid flies of the genera *Mediosetiger* and *Ormia*, a mere 200 and 500 µm, respectively (Robert, D. and Huber, D. unpublished observation). For *Ormia*, such short ID implies ITDs no larger than 1.5 µs (Robert, D. *et al.*, 1996). The body size of these flies does not exceed 2–4 mm, a much shorter distance than the 67 mm wavelength of the biologically relevant sounds – the songs of the cricket hosts they hunt (Robert, D. *et al.*, 1992). In the absence of measurable diffraction, no IID is available as a cue. Several studies have evaluated the effects of diffraction around the body of an insect, including moths (Payne, R. *et al.*, 1966), locusts (Robert, D., 1989), grasshoppers (Michelsen, A. and Rohrseitz, K., 1995), and flies (Robert, D. *et al.*, 1999). It was thus shown that the pressure differences around the insect, and occasionally at the tympanal membranes, increase with sound frequency. The physical aspects of sound propagation and directional auditory cues as applied to insects have specifically been explored in earlier reviews (Michelsen, A., 1992; 1996; 1998; Robert, D. and Hoy, R. R., 1998). Research thus far has established the existence of three main types of tympanal receivers in insects: the pressure receivers, the pressure difference receivers, and the mechanically coupled receivers. How these different types of receivers operate will be presented in the following sections.

3.41.3.4 Directional Hearing Using Pressure Receivers

In pressure receivers, by definition, sound pressure acts only on one side of the tympanal membrane, usually the external one (Miller, L. A., 1977; Michelsen, A., 1998). Pure pressure receivers are found on insects whose bodies are large compared to the wavelength of the sound they detect. These sounds can be the high-frequency echolocation signals of hunting bats, or conspecific songs. For some bushcrickets such songs can reach frequencies above 100 kHz (Montealegre-Z, F., 2006) and can therefore generate significant diffraction around a millimeter-size animal. This way, pressure receiver ears located on each side of the animal experience interaural pressure differences that can constitute sufficient cues for directional hearing. Large diffraction-based IIDs (20–40 dB) were first measured at the ears of noctuid moths, when exposed to the ultrasonic echolocation calls of bats (30–60 kHz) (Payne, R. *et al.*, 1966). In small grasshoppers, much smaller IIDs (1–2 dB) are sufficient to elicit reliable orientation toward attractive intraspecific calling song. As stated before, diffraction-based cues decrease with decreasing frequency. This physical constraint has possibly been shaping the high-frequency calls of many insect species (Michelsen, A., 1996; Bennet-Clark, H. C., 1998). It is important to note here that the actual sound pressures at the ears have rarely been measured with high accuracy, a technical limitation due to the large size of precision microphones relative to the tympanal ear of an insect (Robert, D. *et al.*, 1999).

3.41.3.5 Directional Hearing Using Pressure Difference Receivers

Pressure difference receivers are typically found in insects with body sizes only a fraction of the

wavelength of interest. Pressure difference receivers were first proposed to be at work in locusts to endow them with directional hearing (Autrum, H., 1940). By definition, such receivers operate under the action of sound pressure on both sides of the tympanal membrane (Autrum, H., 1940; Michelsen, A., 1992). Anatomically and functionally, pressure difference receivers are more complicated than pressure receivers; they are endowed with two or more acoustic inputs. These additional inputs serve to guide sound pressure to the internal side of the tympanum. As they propagate in a thin tracheal tube and/or across air sacs, sound waves attenuate to different degrees, or get amplified, and even experience some delays (phase shifts) due to changes in the propagation velocity of sound in confined environments. The force driving the tympanal membrane is the difference between the external and internal pressures acting on the tympanal membrane. When internal and external sound pressures are identical in timing and magnitude, they cancel each other so that no driving force is exerted. When the pressures are equal but of opposite phase, the driving force is maximal, similar to the classic case of constructive (as opposed to destructive) interference between periodic functions. For some pressure difference receivers, the two, bilaterally symmetric ears are coupled by an acoustically conductive tissue, usually a large air sac. In this case, the pressure acting on the internal side of one tympanal membrane originates from the other, contralateral ear. This type of ear is at work in the locust (Miller, L. A., 1977); it operates as a pressure difference receiver for low frequencies but as a pressure receiver for high frequencies.

Bushcrickets have their tympanal ears on the tibia of the foreleg and display another type of pressure difference receivers. Bushcrickets can be much larger than the wavelengths of their usually broadly tuned calling songs. Borne on thin legs, the tympana are unlikely to experience direct and significant diffractive effects. The animal's body, however, is large and dense enough to generate diffractive effects. In this case, the tour de force has been to exploit such effects by conducting the IIDs and ITDs due to the body's presence in the sound field to the sensory cells through a set of horn-shaped tracheal tubes. This system's dominant acoustic inputs are specialized spiracles and horn-shaped atria and trachea leading to the internal side of the tympanal membranes and also to the mechanoreceptive organ (Michelsen, A., 1998). Remarkably, the pressures acting on either side of the tympanum can originate from the same side of the body. This type of pressure difference receiver has not received much biomechanical attention, and while sound amplification in the horn-shaped acoustic trachea has been characterized, the exact action of acoustic pressure on the mechanoreceptor organs is not known.

A further example of pressure difference receivers is that of the field cricket *Gryllus bimaculatus* (Michelsen, A. *et al.*, 1994). For *G. bimaculatus*, body size is less than 1 cm and the wavelength of the calling song is about 7 cm, a strong indication that the ITDs and IIDs are small in this species. The morphology of the auditory organ in field crickets is complex; it encompasses four separate inputs and one internal interaural transmission channel. The reader is encouraged to consult the original article by Michelsen A. *et al.* (1994) to appreciate the sophistication of the cricket's auditory system. In field crickets, the way mechanical energy is conducted from the tympanal system to the mechanosensory organ is not fully understood (Yack, J. E., 2004). In particular, it is unclear how tympanal vibrations determine the mechanical activation of the sensory organ in both magnitude and phase.

3.41.3.6 Directional Hearing Using Mechanically Coupled Pressure Receivers

Directional hearing in the parasitoid fly *O. ochracea* takes yet another, smaller dimension. These flies use their ears to detect, in the pressure field, the songs of their host, field crickets, upon which they deposit their larvae (Cade, W. H., 1975). In all flies of the genus *Ormia* observed to date (Huber, D. and Robert, D. unpublished) the auditory organs are situated on the prothorax, behind the head, and are smaller than 1 mm in size. In effect, the best possible ITD was measured to be 1.45 μs (SD: ±0.49, $N = 10$; Robert, D. *et al.*, 1996). For a small fly, hearing the song of a field cricket at 4.8 kHz, body size to wavelength ratio of 1:35, precludes significant diffractive effects (Robert, D. *et al.*, 1996; 1999). Several studies demonstrated, in field and laboratory conditions, that the fly locates her host, a field cricket singing its calling song or a loudspeaker (Cade, W. H., 1975), using tympanal auditory organs (Robert, D. *et al.*, 1992), and with high accuracy (Müller, P. and Robert, D., 2001). Another series of studies has established the morphology and ultrastructure of the auditory organ (Edgecomb, R. S. *et al.*, 1995) and revealed the mechanism by which directionality is achieved (Miles, R. N. *et al.*, 1995; Robert, D. *et al.*, 1996). It is

achieved by mechanically coupling two adjacent tympanal membranes (Miles, R. N. *et al.*, 1995; Robert, D. *et al.*, 1996). This is an unconventional mechanism that is known to occur only in flies (Robert, D. and Hoy, R. R., 1998). Using scanning laser Doppler vibrometry, it could be shown that mechanical coupling of tympanal membranes has the effect of amplifying tiny acoustic cues into larger interaural differences that can be processed by the nervous system. In response to the host cricket song (carrier frequency at 4.8–5 kHz), the mechanical response of this coupled tympanal system is asymmetrical, resulting from the linear combination of two resonant modes of vibration (for details see Miles, R. N. *et al.*, 1995; Robert, D. *et al.*, 1996; 1998). Remarkably, the mechanical ITD measured between the tympanal membranes is 50–60 µs and the mechanical IID is 3–12 dB for sounds delivered at 90° to the side of the animal. This mechanical ITD is thus about 40 times longer than the 1.5 µs acoustical ITD due to the ID of 520 µm. Converting time difference back into distance (owing to a 344 m s^{-1} propagation velocity of sound in air), it is as if the female tachinid *O. ochracea* had her ears set 1 cm on each side of her body.

Mechanically coupled ears are not unique to tachinid flies; they have also been described in the sarcophagid fly *Emblemasoma* spp. (Robert, D. *et al.*, 1999), an acoustic parasitoid of cicadas. This fly possesses a hearing organ on its prothorax. As a case of evolutionary convergent evolution, this auditory organ is analogous to that of the tachinid fly *O. ochracea*, but its mode of operation is not identical (Robert, D. *et al.*, 1999). The tachinid and sarcophagid auditory systems achieve directional hearing by the asymmetrical deflections of their coupled tympanal membranes. These two systems, however, present several anatomical differences that result in different mechanical responses. Yet, both types of ears give rise to interaural differences in time and amplitude that are essential cues for direction hearing (Robert, D. and Hoy, R. R., 1998). Briefly, in the tachinid system, intertympanal coupling is achieved by the presternum, an unpaired sclerite that spans the midline, where it is anchored to the immobile probasisternum. It was shown that this sclerite acts as mechanical lever coupling the two ears. The lever consists of two beams that are joined medially by a torsional spring and supported by a fulcrum that serves as an immobile pivot point. At the frequency of the cricket song, the presternum undergoes a rocking motion about the fulcrum (with some flexion at the immobile fulcrum), in such a way that one side of the lever moves much more than the other (Miles, R. N. *et al.*, 1995; Robert, D. *et al.*, 1996). The side of the coupled ears that moves more is ipsilateral to the sound source. The sarcophagid ears achieve a similar motion, yet without an immobile, median fulcrum. The tympanal membranes join at the midline of the animal and are creased horizontally, providing the rigidity necessary to the bilateral rocking motion that introduces intertympanal asymmetry (Robert, D. *et al.*, 1999). Hence, through functionally convergent but anatomically divergent evolutionary innovations, these two fly families have independently solved the problem of the directional detection of low-frequency sounds by tympanal membranes separated by a fraction (1:130) of the wavelength. In another genus of tachinid fly, *Therobia*, ears have also been described that detect the calling songs of their bush-cricket hosts singing at somewhat higher frequencies (10–15 kHz) (Lakes-Harlan, R. and Heller, K.-G., 1992). The morphology of these ears clearly indicates that mechanical coupling between tympana is also at work in *Therobia* flies.

3.41.4 Microsecond-Range Acoustic Events and Neural Responses

The capacity of insects to encode auditory information has a long history of research that is discussed in recent authoritative reviews by Pollack G. S. (1998), Hennig M. *et al.* (2004), and Hedwig B. (2006). Some information about the neuronal aspects of directional hearing is also provided in Robert D. and Göpfert M. C. (2002). It is, however, worth noting here that the coding of acoustic information is a fast process. As seen above, mechanical processing amplifies the cues available in the time domain, yet these cues remain very small, even by human standards (Middlebrooks, J. C. and Green, D. M., 1991). Even amplified by about 40 times, the mechanical ITDs are still very small (50–60 µs) and must somehow be encoded by the fly's auditory system. On the basis of neurophysiological and behavioral evidence, a study has shown that the flies can use temporal sound cues at the submicrosecond scale (Mason, A. C. *et al.*, 2001). Walking on an air-cushioned treadmill, flies could be induced to move toward a sound source off the midline by only 2°. Such small angle, given the extremely short ID of *O. ochracea* (520 µm), corresponds to acoustical ITDs of 50 ns (Mason, A. C. *et al.*, 2001). In a series of arduous experiments, the activity, and especially the exact

timing of primary afferent receptor neurons, was measured as a function of the angle of azimuth of the incident sound (Mason, A. C. *et al*., 2001; Oshinsky, M. L. and Hoy, R. R., 2002). Notably, for sounds delivered 90° off the midline, neuronal interaural time delays were measured to be about 150 μs and predicted to be 7 μs at 2° azimuth (Mason, A. C. *et al*., 2001). Importantly, the absolute time to spiking (the delay to the stimulus) was extremely regular and its variation thus remarkably small (3.164 ± 0.095 ms (SD), range 0.012–0.121 ms, $N = 7$). This indicates that the accuracy of the temporal coding is about 10 times larger than the actual neuronal ITDs for the smallest angle resolved (i.e., 0.007 ms at 2°). Entering reasonable speculation at this stage, it was proposed (Mason, A. C. *et al*., 2001) that the fly's auditory system achieves the acuity necessary by pooling a population of afferent neurons onto the first auditory interneurone. Neuroanatomically, the convergence of the fly's 50–100 sensory afferents has not been confirmed. It is known, however, that a large portion of these primary afferent neurons display highly accurate signaling, with only one single sharp and accurate spike per stimulus (Oshinsky, M. L. and Hoy, R. R., 2002). To appreciate more how this process of sensory convergence can generate hyperacute detection capacity in the time domain (de Ruyter van Steveninck, R. R. *et al*., 1977), the reader is invited to consult the articles that suggest this process for the fly *Ormia* (Mason, A. C. *et al*., 2001; Oshinsky, M. L. and Hoy, R. R., 2002) and for electric fish, notably (Rose, G. and Heiligenberg, W., 1985).

3.41.5 Conclusion

Many questions remain unanswered in insect directional hearing. Do insects possess a capacity for auditory scene analysis, which they could use to navigate within their environment in space and time? Some behavioral experiments on the fly *Ormia* (Müller, P. and Robert, D., 2001) and on crickets (Wyttenbach, R. A. and Hoy, R. R., 1997) have suggested the possibility that some insects may acquire three-dimensional auditory information about their position relative to a sound source. This capacity has not been tested in other insect species, nor have neuronal mechanisms been considered. Since the capacity for auditory space perception is generally attributed to large-brained animals (Knudsen, E. I. and Konishi, M., 1979), it would be most interesting to establish whether insect neuronal coding of directionality bears any resemblance, or convergence, to coding in vertebrate auditory specialists. More generally, research into insect sensory systems has never failed to enrich, by matter of comparison and analogy, our knowledge of the senses, including our own, inasmuch as insects have also never failed to impress the researchers with their surprisingly diverse evolutionary creativity.

Glossary

amygdala A complex of subcortical cell groups located deep within the temporal lobe; thought to play a role in emotional responses, especially fear.

anterograde tracer A substance that, when placed in a specific region of the brain, is taken up by neuron cell bodies and transported to their axon terminals where it remains for some time. The distribution of the substance can then be visualized histologically by performing a chemical reaction that produces a colored product or through the use of fluorescence microscopy.

anteroventral cochlear nucleus (AVCN) One of two divisions of the ventral cochlear nucleus; receives direct input from the auditory nerve and provides the main ascending pathway to the principal nuclei of the superior olivary complex and the intermediate and ventral nuclei of the lateral lemniscus; also provides direct projections to the inferior colliculus.

binaural Receiving and/or responding to input from both ears.

brachium of the inferior colliculus (BIC) Bundle of fibers running from the inferior colliculus to the medial geniculate nucleus.

central nucleus of the inferior colliculus The ventromedial and central portion of the inferior colliculus that receives direct projections from the anteroventral cochlear nucleus.

cochlear nucleus The first structure in the central nervous system to receive auditory input, via the auditory nerve. The cochlear nucleus contains three complete tonotopic representations and gives rise to multiple parallel pathways in the brainstem.

corticofugal projections Projections that descend from the cortex to innervate a subcortical structure such as the medial geniculate or inferior colliculus.

cuneate nucleus Cell group in the lower brainstem that receives somatosensory input via the spinal cord.

delay lines Multiple inputs to a single target neuron, each of which has a slightly different latency (delay of response relative to stimulus onset).

dorsal cochlear nucleus (DCN) One of two major anatomical divisions of the cochlear nucleus; receives direct input from the auditory nerve as well as descending input from a variety of sources.

dorsal column nuclei Cell groups in the lower brainstem that receive somatosensory input via the dorsal column pathway of the spinal cord.

dorsal cortex of the inferior colliculus The region dorsomedial to the central nucleus.

dorsal nucleus of the lateral lemniscus (DNLL) A group of neurons located just below the inferior colliculus. The DNLL receives input from the ipsilateral medial superior olive, the lateral superior olive bilaterally, and the opposite DNLL. It projects bilaterally to the inferior colliculus.

dorsal raphe nuclei A group of cell bodies located along the midline below the periaqueductal gray. The main source of serotonergic fibers, which have diffuse and widespread projections throughout the rest of the brain.

external nucleus of the inferior colliculus The region lateral to the central nucleus.

fibrodendritic lamina An anatomical module within the inferior colliculus consisting of ascending fibers from the lower brainstem, intrinsic projections, cell bodies, and dendrites. A fibrodendritic lamina is thought to correspond to a functionally defined isofrequency contour.

frequency sweep (frequency modulation (FM)) A tonal stimulus, the frequency of which changes continuously from beginning to end.

globus pallidus Group of neuron cell bodies that is a major component of the basal ganglia system, and is involved in motor control.

inferior colliculus The principal midbrain auditory center in mammals. Integrates inputs from a variety of sources; projects to the thalamocortical system and motor-related pathways.

intermediate nucleus of the lateral lemniscus (INLL) A group of cell bodies located between the ascending fibers of the lateral lemniscus, between the dorsal and ventral nuclei of the lateral lemniscus. It receives input mainly from the contralateral anteroventral cochlear nucleus and projects to the ipsilateral inferior colliculus.

intrinsic connections (projections) Connections among neurons within a brain structure.

iontophoretic Using a small current of the same polarity as a charged molecule to eject the substance from a micropipette.

isofrequency lamina A region of an auditory structure (e.g., inferior colliculus) in which all neurons have similar best frequencies.

lateral superior olive (LSO) Cell group belonging to the superior olivary complex. LSO receives excitatory input from the ipsilateral cochlear nucleus and inhibitory input from the contralateral cochlear nucleus via a synapse in the medial nucleus of the trapezoid body; cells in LSO are sensitive to small interaural intensity differences corresponding to the location of a sound source in the horizontal plane.

locus coeruleus A group of noradrenergic cell bodies located in the dorsal and rostral part of the brainstem; provides diffuse and widespread noradrenergic projections throughout the brain.

medial geniculate body The main thalamic structure of the auditory system; receives input from the inferior colliculus and has reciprocal connections with primary auditory cortex.

medial superior olive (MSO) Cell group belonging to the superior olivary complex. In mammals with good low-frequency hearing, MSO receives excitatory input from both cochlear nuclei; cells in MSO are sensitive to small interaural time differences corresponding to the location of a sound source in the horizontal plane.

modulation rate The frequency with which a stimulus parameter is changed, usually expressed in Hz (cycles s^{-1}). Often used to describe sinusoidal frequency or amplitude modulations of a tone.

monaural Receiving and/or responding to input from one ear only.

novelty responses The property of responding exclusively, or in an enhanced manner, to a novel stimulus.

nuclei of the lateral lemniscus (NLL) A group of nuclei in the lower brainstem that includes the dorsal nucleus of the lateral lemniscus (DNLL), the intermediate nucleus of the lateral lemniscus (INLL) and the ventral nucleus of the lateral lemniscus (VNLL). The DNLL receives input from the superior olivary complex and is a binaural structure; the INLL and VNLL receive input from the contralateral cochlear nucleus and are mainly monaural structures. All divisions of the NLL project to the inferior colliculus.

nucleotopic An organization in which projections from different cell groups (nuclei) terminate in segregated areas within a single anatomically defined target structure.

nucleus incertus A group of neuron cell bodies in the ventral and caudal part of the periaqueductal gray. Possibly involved in integrating sensory input with behavioral planning and/or arousal.

periaqueductal gray (also called the central gray) Group of neuron cell bodies that surround the

cerebral aqueduct; center for integration of sensory and motor information from multiple systems.

peripeduncular nucleus Group of neuron cell bodies located adjacent to the medial geniculate nucleus; may be involved in processing sensory stimuli during emotional situations.

pontine gray A heterogeneous group of neuron cell bodies located in the rostral part of the lower brainstem; receives input from a variety of sources including the visual and auditory systems and projects to the cerebellum.

posterior intralaminar nuclei Group of neuron cell bodies located adjacent to the medial geniculate nucleus; project to auditory cortex and amygdala and may be involved in processing sensory stimuli during emotional situations.

posterior limitans nucleus Group of neuron cell bodies that is part of the posterior nuclear complex of the thalamus, and may be involved in integration of information from multiple sensory modalities.

pericentral nucleus of the inferior colliculus The regions surrounding the central nucleus.

posteroventral cochlear nucleus (PVCN) One of two divisions of the ventral cochlear nucleus. Receives direct projections from the auditory nerve and projects mainly to periolivary cell groups.

sinusoidal amplitude modulation (SAM) Periodic change in the amplitude of a stimulus according to a sine wave function.

sinusoidal frequency modulation (SFM) Periodic change in the frequency of a stimulus according to a sine wave function.

somatosensory cortex The portion of the neocortex that processes sensory information about touch, pressure, temperature, pain, and other cutaneous and somatic sensory modalities.

spinal trigeminal nucleus A group of neuron cell bodies in the lower brainstem that receive somatosensory input via the trigeminal nerve.

stimulus-specific adaptation A decrement in response to a stimulus presented repeatedly; does not generalize to other similar stimuli, provided there is a change in at least one parameter.

subparafascicular nucleus Group of neuron cell bodies in the posterior thalamus, thought to be a site for integration of auditory and nociceptive information.

substantia nigra Group of neuron cell bodies in the ventral midbrain that is part of the basal ganglia system and plays a role in motor control.

superior colliculus Midbrain center that receives input from visual system, auditory system, and other sensory systems and is involved in orienting reflexes.

superior olivary complex (SOC) A group of nuclei in the lower brainstem that includes the lateral superior olive (LSO), medial superior olive (MSO), medial nucleus of the trapezoid body (MNTB), and a number of periolivary cell groups. In most mammals the principal nuclei of the SOC (MSO and LSO) perform comparisons of sound at the two ears.

trigeminal nucleus Complex of sensory and motor neurons serving the trigeminal (fifth cranial) nerve.

ventral cochlear nucleus (VCN) One of two major anatomical divisions of the cochlear nucleus; receives direct input from the auditory nerve; comprises the anteroventral and posteroventral cochlear nuclei.

ventral nucleus of the lateral lemniscus (VNLL) A group of neuron cell bodies located between the ascending fibers of the lateral lemniscus, just ventral to the intermediate nucleus. The VNLL receives input from the contralateral anteroventral cochlear nucleus and ipsilateral medial nucleus of the trapezoid body. It projects to the ipsilateral inferior colliculus.

vestibular nuclei Groups of neuron cell bodies in the lower brainstem that receive input related to balance and acceleration from the vestibular system via the vestibular branch of the eighth cranial nerve.

3.42.1 Sources of Ascending Inputs to the Inferior Colliculus

The inferior colliculus (IC) receives a diverse assortment of inputs from multiple sources. These include monaural and binaural ascending pathways as well as intrinsic, descending, motor-related, polysensory, and modulatory inputs. The anatomical details of the main auditory pathways to the IC have been described in a number of previous reviews (e.g., Covey, E. and Casseday, J. H., 1995; Casseday, J. H. *et al.*, 2002; Cant, N. B. and Benson, C. G., 2003; Covey, E. and Carr, C. E., 2004; Cant, N. B., 2005; Saldana, E. and Merchan, M. A., 2005; Schofield, B. R., 2005; Winer, J. A., 2005), and are summarized in Figure 1. The various pathways have usually been

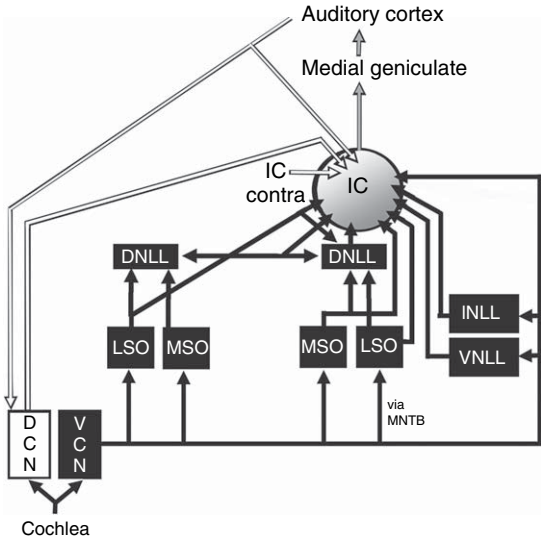

Figure 1 Block diagram illustrating the major auditory pathways to the inferior colliculus (IC). Direct and indirect pathways originating in the ventral cochlear nucleus (VCN system) are shown in black, those originating in the DCN, auditory cortex, and opposite IC (DCN system) are shown in white. Shading in the IC illustrates the dominance of the DCN system dorsally and the VCN system ventrally. DNLL, dorsal nucleus of the lateral lemniscus; INLL, intermediate nucleus of the lateral lemniscus; LSO, lateral superior olive; MNTB, medial nucleus of the trapezoid body; MSO, medial superior olive; cochlear nucleus; VNLL, ventral nucleus of the lateral lemniscus.

considered individually rather than as an integrated system, so this chapter will focus on evidence for graded patterns of input and the nature of the anatomical relationships among the various pathways. It will also briefly consider the possible functional consequences of interactions among different sources of input with graded patterns of distribution.

Although many studies in the past have been based on the hypothesis that the inputs from different sources are segregated within the IC, the evidence that has accumulated to date overwhelmingly indicates that there is at least some degree of overlap in every region of the IC, with inputs from each source forming density gradients throughout one or more spatial dimensions. The functional implication of this organizational principle is that neurons in every part of the IC have the opportunity to integrate information that originates in different pathways. In fact, such integration must be a major function of the IC (Casseday, J. H. and Covey, E., 1996). The relative contributions of all of the different pathways vary across the extent of the IC so that, functionally, each point within the IC lies at a set of coordinates in a multidimensional matrix in which the inputs from different sources have a unique ratio in terms of their strengths.

3.42.2 Parsing the Pathways to the Inferior Colliculus

The principal source of input to the IC is, of course, the ascending system of projections from the brainstem auditory nuclei (Figure 1). These include dense projections from the cochlear nucleus directly, as well as indirectly via the superior olivary complex (SOC) and nuclei of the lateral lemniscus (NLL). Because the indirect pathways via the SOC and NLL involve one or more additional synapses, it is likely that they provide a longer range of latencies than does the cochlear nucleus (Haplea, S. *et al.*, 1994).

3.42.2.1 Direct and Indirect Pathways

Because of the complexity of the ascending auditory inputs, it is possible to group these projections into different systems depending on what criterion is applied. For example, we can think of the inputs to the IC as forming direct and indirect systems of pathways in which those from the different subdivisions and cell types of the contralateral cochlear nucleus provide a fast, relatively unprocessed view of the incoming information, while those via the SOC and NLL provide a view that has been processed at one or more stages to extract information about binaural differences or specific features of temporal patterns.

3.42.2.2 Binaural and Monaural Pathways

An even more frequent way of parsing is to group ascending inputs to the IC into binaural and monaural pathways, a sort of auditory analog of the what and where pathways in the visual system, with binaural inputs originating in the SOC and dorsal nucleus of the NLL (DNLL), and monaural inputs originating in the contralateral cochlear nucleus and the intermediate and ventral nuclei of the NLL (INLL and VNLL, respectively). Both of these views are based on solid evidence, and are unquestionably valid. However, they are not without their limitations. For example, it is doubtful that the dorsal cochlear nucleus (DCN), which provides a direct pathway to the IC, conveys a simple, primarylike view of the auditory stimulus given that it receives

polysensory input as well as a significant amount of descending input from the auditory cortex (e.g., Ryugo, D. K. *et al.*, 2003). The distinction between binaural and monaural pathways is somewhat blurred for several reasons. A given pathway may be binaural or monaural depending on species, the best example being the medial superior olive (MSO), which is binaural in carnivores and rodents and monaural in some species of bats (for review, see Grothe, B. and Park, T. J., 2000). Pathways that are traditionally considered monaural are almost without exception known to receive at least some binaural input, one example being crossed projections from one anteroventral cochlear nucleus (AVCN) to the other (e.g., Schofield, B. R. and Cant, N. B., 1996).

3.42.2.3 Gradient Systems of Pathways

A different way to parse the inputs to the IC is in terms of the density gradients that they form. There is considerable evidence that the projections to the IC take the form of at least two opposing gradients approximately orthogonal to the main tonotopic progression, a DCN system in which the density of projections decreases from dorsomedial to ventrolateral, and a ventral cochlear nucleus (VCN) system, in which the density decreases from ventrolateral to dorsomedial. The following sections will present evidence for this system of gradients, review what is known about the finer grained organization of axon terminals from different sources within each system and between the two systems, and consider some of the integrative processes that might result.

3.42.3 Projection Gradients in the Inferior Colliculus

3.42.3.1 The Ventral Cochlear Nucleus System

The bulk of the projections from the different subdivisions and projecting cell types of the contralateral cochlear nucleus terminate in a partially to completely overlapping fashion in the central nucleus of the IC. Depending on species, the projections may extend to a greater or lesser extent into areas outside the central nucleus (e.g., Ryugo, D. K. *et al.*, 1981; Zook, J. M. and Casseday, J. H., 1982; Willard, F. H. and Martin, G. F., 1983; Oliver, D. L., 1984; Whitley, J. M. and Henkel, C. K., 1984; Oliver, D. L., 1985; Zook, J. M. and Casseday, J. H., 1985; Coleman, J. R. and Clerici, W. J., 1987; Zook, J. M. and Casseday, J. H., 1987; Oliver, D. L. *et al.*, 1997; Oliver, D. L. *et al.*, 1999). There is little evidence in any species that would suggest a strictly nucleotopic projection pattern, or one in which inputs are strictly segregated into different regions of the IC. Figures 2 and 3 show results of an early experiment in the mustached bat in which the distribution of projections from the VCN was compared with that of projections from the DCN (Zook, J. M. and Casseday, J. H., 1985). These authors found that although there is a small dorsal portion of the IC that receives input only from DCN, the projections from the posteroventral cochlear nucleus (PVCN), AVCN, and DCN overlap throughout most of the IC. Despite the extensive overlap, the projections from the VCN and DCN form gradients of opposite density, with the projections of DCN most dense dorsally and those from VCN most dense ventrally. This pattern has been confirmed in other mammalian species (for review see Casseday, J. H. *et al.*, 2002).

Although both VCN and DCN receive direct input from the cochlea via branches of the auditory nerve as well as some descending input from auditory nuclei higher in the central pathway, their structure, connections, and response properties are in many respects quite

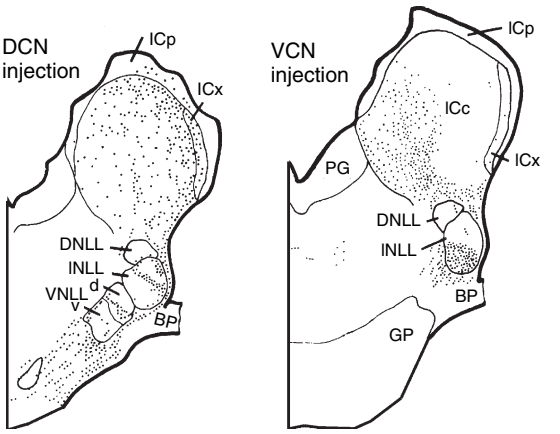

Figure 2 Distribution of label in the inferior colliculus (IC) after injections of anterograde tracers in the contralateral dorsal cochlear nucleus (DCN; left) and ventral cochlear nucleus (VCN; right). Both are frontal sections through the right side of the brain of the mustached bat, *Pteronotus parnellii*. BP, brachium pontis; DNLL, dorsal nucleus of the lateral lemniscus; GP, pontine gray; ICc, central nucleus of the IC; ICp, pericentral nucleus of the IC; ICx, external nucleus of the IC; PG, periaqueductal gray; VNLLd, dorsal division of the ventral nucleus of the lateral lemniscus; VNLLv, ventral division of the ventral nucleus of the lateral lemniscus. Adapted from Zook, J. M. and Casseday, J. H. 1985. Projections from the cochlear nuclei in the mustache bat, *Pteronotus parnellii*. J. Comp. Neurol. 237, 307–324.

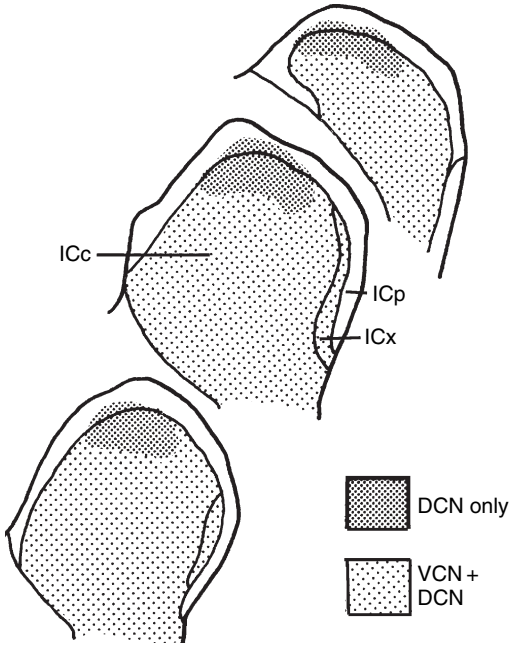

Figure 3 Summary diagram showing regions of the inferior colliculus (IC) that receive projections from both ventral cochlear nucleus (VCN) and dorsal cochlear nucleus (DCN; light shading) or DCN only (dense shading). Frontal sections through the right IC are arranged rostral to caudal, from top to bottom. ICc, central nucleus of the IC; ICp, pericentral nucleus of the IC; ICx, external nucleus of the IC. From Zook, J. M. and Casseday, J. H. 1985. Projections from the cochlear nuclei in the mustache bat, *Pteronotus parnellii*. J. Comp. Neurol. 237, 307–324.

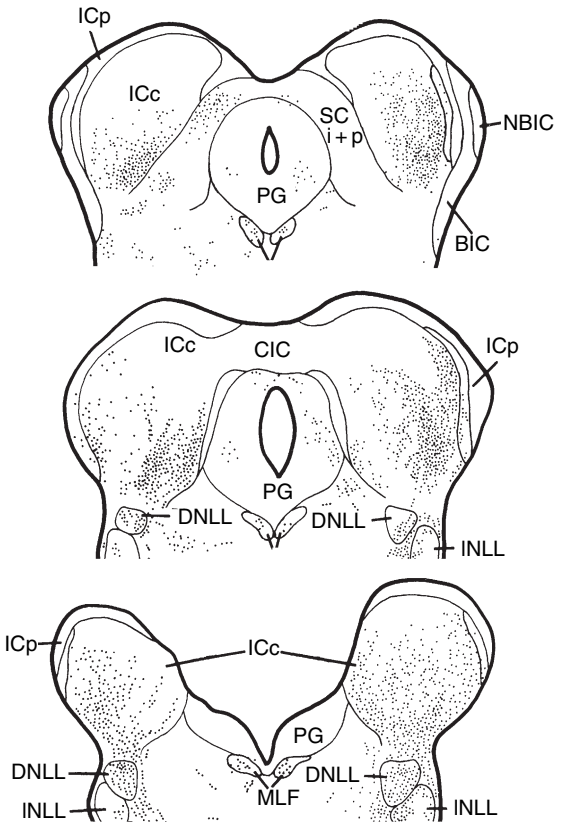

Figure 4 Distribution of anterograde label in the inferior colliculus (IC) bilaterally after an injection into part of the right medial superior olive (MSO) and lateral superior olive (LSO). Frontal sections through the brainstem of the mustached bat, arranged rostral to caudal, from top to bottom. BIC, brachium of the IC; CIC, commissure of the IC; DNLL, dorsal nucleus of the lateral lemniscus; i + p, intermediate and deep layers; ICc, central nucleus of the IC; ICp, pericentral nucleus of the IC; INLL, intermediate nucleus of the lateral lemniscus; MLF, medial longitudinal fasciculus; NBIC, nucleus of the brachium of the IC; PG, periaqueductal gray; SC, superior colliculus. Adapted from Zook, J. M. and Casseday, J. H. 1987. Convergence of ascending pathways at the inferior colliculus of the mustache bat, *Pteronotus parnellii*. J. Comp. Neurol. 261, 347–361.

different. The output of the VCN more closely reflects that of the auditory nerve than does that of the DCN, which receives descending input from the auditory cortex (Weedman, D. L. and Ryugo, D. K., 1996; Jacomme, A. V. *et al.*, 2003; Schofield, B. R. and Coomes, D. L., 2005) and the IC itself (e.g., Alibardi, L., 1999) as well as a variety of sources outside the auditory system (for a review, see Ryugo, D. K. *et al.*, 2003), including the dorsal column and cuneate nuclei, spinal trigeminal nuclei, somatosensory cortex (Itoh, K. *et al.*, 1987; Wright, D. D. and Ryugo, D. K., 1996; Li, H. and Mizuno, N., 1997; Wolff, A. and Kunzle, H., 1997; Zhou, J. and Shore, S., 2004; Haenggeli, C. A. *et al.*, 2005), vestibular nuclei (Bukowska, D., 2002), and pontine gray (Ohlrogge, M. *et al.*, 2001).

The opposing gradients in density of projections within the IC form the basis of a VCN system of projections in which density decreases from ventrolateral to dorsomedial, and a second, DCN system in which density decreases from dorsomedial to ventrolateral (Casseday, J. H. *et al.*, 2002). The inputs from the two systems overlap throughout much of the IC, albeit with different relative densities. This scheme becomes especially useful as an organizing principle when projections from other sources are added to the mix. Those structures that receive an input directly from the VCN, mainly the SOC and the NLL, all project to the IC in a gradient fashion similar to the direct projections from VCN, with the highest density ventrally (e.g., Vater, M. *et al.*, 1995; Oliver, D. L. *et al.*, 1997; Loftus, W. C. *et al.*, 2004). For easy comparison with the projections from the cochlear nucleus, Figure 4 shows an example of the pattern of labeled

terminals from a large injection of an anterograde tracer in the SOC in the mustached bat. The area containing label and the ventrolateral to dorsomedial density gradient are very similar to those seen after injections in the AVCN. Figure 5 shows an example, again from the mustached bat, of the pattern of labeled terminals resulting from an injection in the NLL. Clearly, if the label from the VCN, SOC, and NLL were superimposed, it would occupy a similar area, with a similar density gradient.

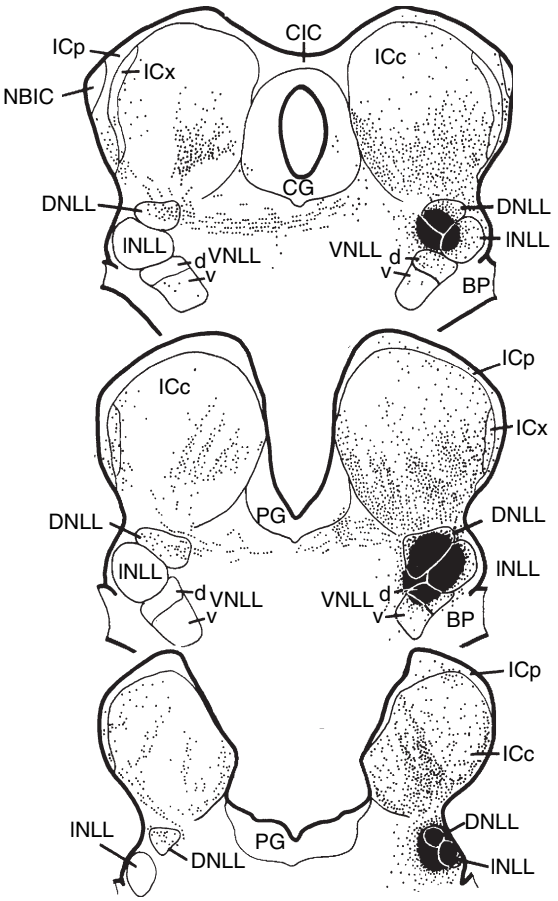

Figure 5 Distribution of anterograde label in the inferior colliculus (IC) bilaterally after an injection into part of the right nucleus of the lateral lemniscus (NLL), including the ventral nucleus of the lateral lemniscus (VNLL), intermediate nucleus of the lateral lemniscus (INLL), and dorsal nucleus of the lateral lemniscus (DNLL). Frontal sections through the brainstem of the mustached bat, arranged rostral to caudal, from top to bottom. BP, brachium pontis; CIC, commissure of the IC; DNLL, dorsal nucleus of the lateral lemniscus; ICc, central nucleus of the IC; ICp, pericentral nucleus of the IC; ICx, external nucleus of the IC; NBIC, nucleus of the brachium of the IC PG, periaqueductal gray. Adapted from Zook, J. M. and Casseday, J. H. 1987. Convergence of ascending pathways at the inferior colliculus of the mustache bat, *Pteronotus parnellii*. J. Comp. Neurol. 261, 347–361.

The current evidence suggests that the ipsilateral MSO and contralateral lateral superior olive (LSO) provide excitatory input to the IC, and the ipsilateral LSO provides glycinergic inhibitory input (e.g., Saint Marie, R. L. *et al.*, 1989; Saint Marie, R. L. and Baker, R. A., 1990; Glendenning, K. K. *et al.*, 1992; Oliver, D. L. *et al.*, 1995; see Oliver, D. L., 2000 for review). The ventral NLL (VNLL) and INLL appear to provide a mixture of excitatory projections, gamma-aminobutyric acid (GABA)ergic inhibitory projections, and glycinergic inhibitory projections, while the dorsal NLL (DNLL) provides a bilateral GABAergic projection (Gonzalez-Hernandez, T. *et al.*, 1996; Vater, M. *et al.*, 1997; Zhang, D. X. *et al.*, 1998). Therefore the VCN system alone provides ample opportunity for direct and indirect excitatory and inhibitory inputs to interact throughout most of the IC.

3.42.3.2 The Dorsal Cochlear Nucleus System

As already shown in Figures 1 and 2, the pathway from DCN terminates most densely in the dorsal part of the IC including the pericentral regions (or dorsal cortex and external nucleus, depending on the nomenclature used). Other pathways that terminate in a pattern similar to that of the DCN projections include the descending projections from multiple subdivisions of the auditory cortex (Herrera, M. *et al.*, 1994; Saldana, E. *et al.*, 1996; Druga, R. *et al.*, 1997; Winer, J. A. *et al.*, 1998; Budinger, E. *et al.*, 2000; Marsh, R. A. *et al.*, 2002; Bajo, V. M. and Moore, D. R., 2005), and the commissural projections from the opposite IC (Gonzalez-Hernandez, T. *et al.*, 1996). The dorsomedial to ventrolateral gradient of the cortical projection to the IC of the rat can be seen in Figure 6. This figure also illustrates the point that the projection does not respect the cytoarchitectural subdivisions drawn by the authors, but rather forms a set of gradients that begin densely in the dorsomedial portion of the IC, extending through the dorsal cortex, external cortex, and central nucleus, becoming less dense ventrolaterally. The corticofugal projections appear to be excitatory (e.g., Saldana, E. *et al.*, 1996), as are those from the DCN (reviewed in Cant, N. B. and Benson, C. G., 2003).

The projections from the opposite IC also form a dorsomedial to ventrolateral density gradient. Figure 7 shows an example of anterograde transport from two small injections in the right IC of the rat (Saldana, E. and Merchan, M. A., 1992). These authors make the

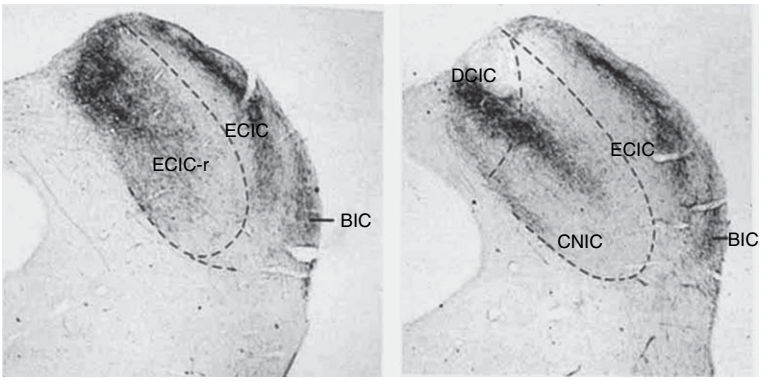

Figure 6 Photomicrographs showing distribution of anterograde label in the inferior colliculus (IC) of the rat after an injection in auditory cortex. Frontal sections through the right IC, arranged rostral to caudal from left to right. BIC, brachium of the IC; CNIC, central nucleus of the IC; DCIC, dorsal cortex of the IC; ECIC, external cortex of the IC; ECIC-r, rostral pole of the external cortex of the IC. Adapted from Saldana, E., Feliciano M., Mugnaini E. 1996. Distribution of descending projections from primary auditory neocortex to inferior colliculus mimics the topography of intracollicular projections. J. Comp. Neurol. 371, 15–40.

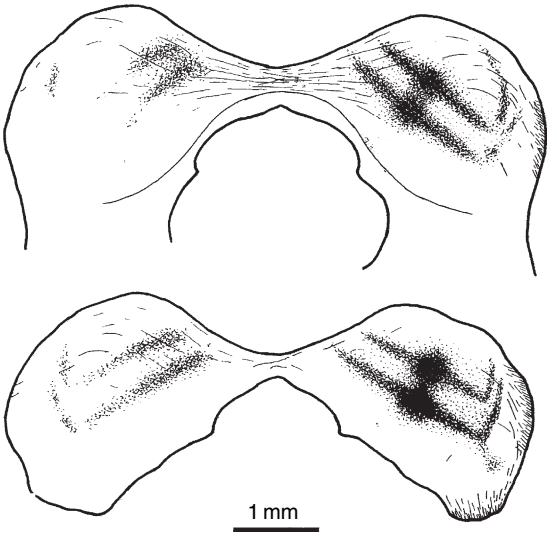

Figure 7 Drawings of frontal sections through the inferior colliculus (IC) of the rat showing 2 small tracer injections on the right side and anterograde transport on the left side. Adapted from Saldana, E. and Merchan, M. A. 1992. Intrinsic and commissural connections of the rat inferior colliculus. J. Comp. Neurol. 319, 417–437.

point that the commissural and corticofugal projections to the IC must overlap extensively. The projections from the opposite IC appear to provide a mixture of glutamatergic excitation and GABAergic inhibition (Gonzalez-Hernandez, T. *et al.*, 1996; Moore, D. R. *et al.*, 1998; Malmierca, M. S. *et al.*, 2003; 2005).

Inputs from nonauditory structures that presumably contribute a modulatory influence include serotonergic inputs from the dorsal raphe nuclei (Klepper, A. and Herbert, H., 1991; Thompson, A. M. *et al.*, 1994; Hurley, L. M. and Thompson, A. M., 2001) and noradrenergic inputs from the locus coeruleus (Klepper, A. and Herbert, H., 1991). Both serotonin and norepinephrine terminals are most dense dorsomedially and in the pericentral areas of the IC, becoming progressively less dense ventrolaterally. Figure 8 shows the distribution of fibers and terminals immmunostained for serotonin. Thus, the distribution of monoamine modulatory transmitters closely follows the DCN system pattern. Interestingly, serotonin terminal density is known to be higher in DCN than in other parts of the cochlear nucleus, suggesting that the entire DCN system of projections is more subject to modulatory influences than the VCN system.

The DCN system provides a system of inputs from areas that presumably represent relatively complex stages of processing. As in the AVCN system, these may be excitatory or inhibitory and more or less direct and, as will be seen below, there is ample opportunity for interaction between the two systems throughout much of the IC.

The IC also receives projections from thalamic regions including the medial division of the medial geniculate body, periaqueductal gray, posterior limitans nucleus, substantia nigra, peripeduncular/suprapeduncular nucleus, subparafascicular and posterior intralaminar nuclei, nucleus of the brachium of the IC, lateral tegmental/lateral mesencephalic areas, and deep layers of the superior colliculus (Winer, J. A. *et al.*, 2002), but the pattern of termination of these pathways within the IC is not clear.

J. 2002. Projection to the inferior colliculus from the basal nucleus of the amygdala. J. Neurosci. 22, 10449–10460.

3.42.3.3 Other Types of Gradients or Distributions

The IC receives some inputs that do not appear to follow the DCN/VCN pattern. For example, the amygdala projects throughout virtually the entire IC, but in a gradient that is low dorsomedially and ventrolaterally, peaking somewhere near the middle (Marsh, R. A. *et al.*, 2002). Figure 9 illustrates the circuit that includes the IC, auditory cortex, and amygdala and makes the point that as in most or all of the other systems discussed here, there are direct and indirect pathways from the auditory cortex to the IC, including a widespread projection via the amygdala. This suggests that responses of neurons in the IC are subject to direct modulation by emotional state.

Other nonauditory influences on IC neurons include inputs from pathways related to motor activity and arousal. In general, these nonauditory pathways have been reported to project to the external cortex (or pericentral region) of the IC. These include the trigeminal nucleus (Kunzle, H., 1998), the globus pallidus (Shammah-Lagnado, S. J. *et al.*, 1996), the nucleus incertus, a structure thought to be involved in arousal (Olucha-Bordonau, F. E. *et al.*, 2003), and the ventrolateral tegmentum, an area that may be involved is sensory–motor integration (Herbert, H. *et al.*, 1997). It is not clear whether these projections are strictly confined to the external cortex, or whether they are simply most dense in that region.

3.42.4 Relationships Among Projections from Different Sources

3.42.4.1 Laminar Projections Within the Anteroventral Cochlear Nucleus System

Although the opposing gradient systems provide a useful general framework in which to consider the organization of the IC, within each system there are additional levels of organization that probably are important for the function of the IC. Many studies have observed that anterograde transport to the IC from injections in single structures that provide

afferent input often takes the form of bands and/or patches. This banding pattern can be seen most clearly in projections from the LSO, MSO, and DNLL, i.e., structures of the binaural system (see Figures 4 and 5). The extent of banding may vary across species, and there may be consistent differences depending on the source of the transport. For example, Shneiderman A. and Henkel C. K. (1987) found that anterograde transport from LSO in the cat formed bands of dense label about 150–200 μm thick, separated by bands of similar thickness that contained little label. The bands paralleled the fibrodendritic laminae of the IC, and presumably the isofrequency laminae. The bands originating from the ipsilateral LSO were prominent while those originating from the contralateral LSO were more diffuse. In cases in which two different anterograde tracers were used, one placed in the LSO of each side, they found that the bands from the two sides interdigitated or partly overlapped, suggesting that there was some segregation of the ipsilateral and contralateral inputs from the two sides within a lamina.

Patterns of projections from the ipsilateral MSO and contralateral LSO have also been compared in the mustached bat using different anterograde tracers (Vater, M. *et al.*, 1995; Figure 10). Projections from frequency-matched areas in the LSO and MSO terminated in much the same regions of the IC, and had a somewhat banded appearance with partial overlap of many of the bands. When viewed in a parasagittal reconstruction, low-frequency projections almost completely overlapped, but for the higher frequencies, the projections from MSO extended somewhat more dorsally and rostrally than those from LSO (Figure 11).

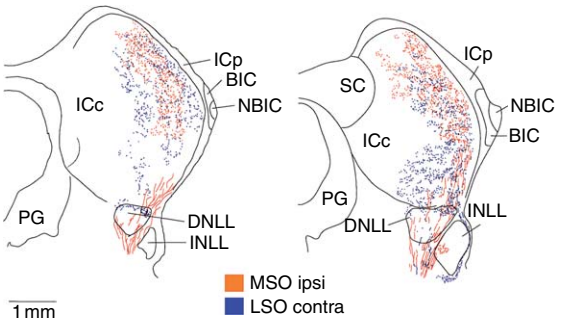

Figure 10 Comparison of the distribution of transport from injections of two anterograde tracers, one in a low-frequency region of the ipsilateral medial superior olive (MSO; orange) and another in a low frequency region of the contralateral lateral superior olive (LSO; blue). Frontal sections through the right inferior colliculus (IC) of the mustached bat, arranged caudal to rostral from left to right. BIC, brachium of the IC; DNLL, dorsal nucleus of the lateral lemniscus; ICc, central nucleus of the IC; ICp, pericentral nucleus of the IC; NBIC, nucleus of the brachium of the IC; PG, periaqueductal gray; SC, superior colliculus. Adapted from Vater, M., Casseday, J. H., and Covey, E. 1995. Convergence and divergence of ascending binaural and monaural pathways from the superior olives of the mustached bat. J. Comp. Neurol. 351, 632–646.

Loftus W. C. *et al.* (2004) added another level of complexity to the analysis of projections from the binaural pathways of the VCN system by comparing the patterns of anterograde transport from the ipsilateral MSO, ipsilateral LSO, and contralateral LSO in the cat. These authors reported that within a fibrodendritic lamina, boutons from MSO terminated mainly in the central and caudal parts of a lamina while those from LSO were more concentrated more rostrally within the lamina, and at the ventral edge of the input from MSO (Figure 12), with a denser and more clearly banded projection from the ipsilateral LSO than from the contralateral.

The projection from the DNLL of cats and ferrets is also banded (Shneiderman, A. *et al.*, 1988; Henkel, C. K. *et al.*, 2003), but in this case, the bands from the contralateral DNLL were found to be prominent while those from the ipsilateral DNLL were more diffuse. This pattern can be seen in the mustached bat in Figure 5, suggesting that it is common across species. Gabriele M. L. *et al.* (2000) found that unilateral cochlear ablation in rat pups disrupts the banded pattern of DNLL afferents in the IC, suggesting that the pattern of banded projections is determined during development by activity-dependent mechanisms.

3.42.4.2 Relation between Dorsal Cochlear Nucleus and Ventral Cochlear Nucleus System Projections

Oliver D. L. *et al.* (1997) examined the relation between projections from the contralateral LSO and DCN of the cat. As in other species, the DCN projection extended farther in the dorsomedial dimension than did that from LSO, but within the more ventral area there was considerable overlap (Figure 13). Measurements made in the regions that contained label from both sources indicated that the LSO axons were coextensive with the DCN axons about 80–90% of the time, but that there were small patches where only one projection was present. On the basis of these findings, the authors proposed a model of functional zones or modules within a fibrodendritic lamina, with DCN dominating dorsally and inputs

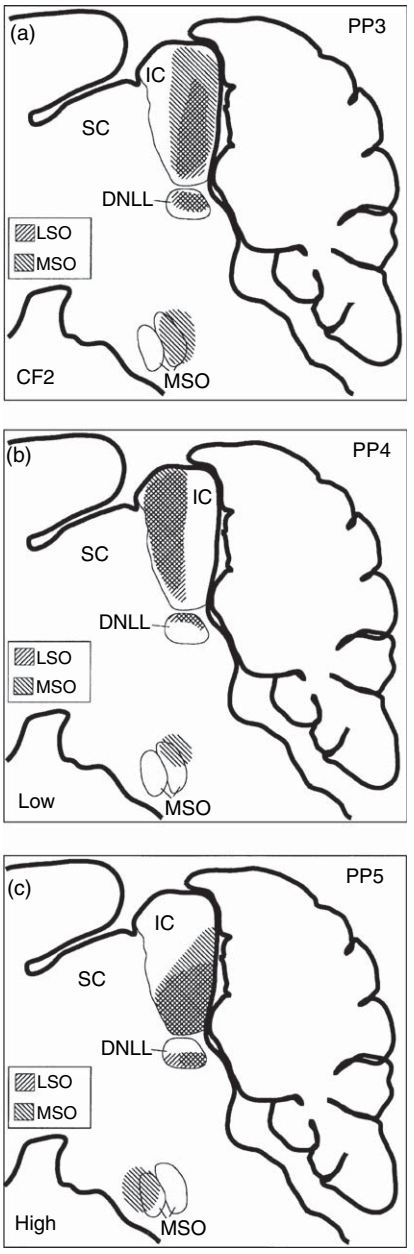

Figure 11 Parasagittal reconstructions to compare the extent of anterograde label from medial superior olive (MSO) and lateral superior olive (LSO) in three different frequency ranges in the inferior colliculus (IC) of the mustached bat. Top panel: CF2 is the frequency of the dominant harmonic of this species' echolocation call (approximately 62 kHz). This frequency occupies an expanded representation at every level of the auditory system. Low frequencies are those below CF2, and high frequencies those above CF2. DNLL, dorsal nucleus of the lateral lemniscus; SC, superior colliculus. From Vater, M., Casseday, J. H., and Covey, E. 1995. Convergence and divergence of ascending binaural and monaural pathways from the superior olives of the mustached bat. J. Comp. Neurol. 351, 632–646.

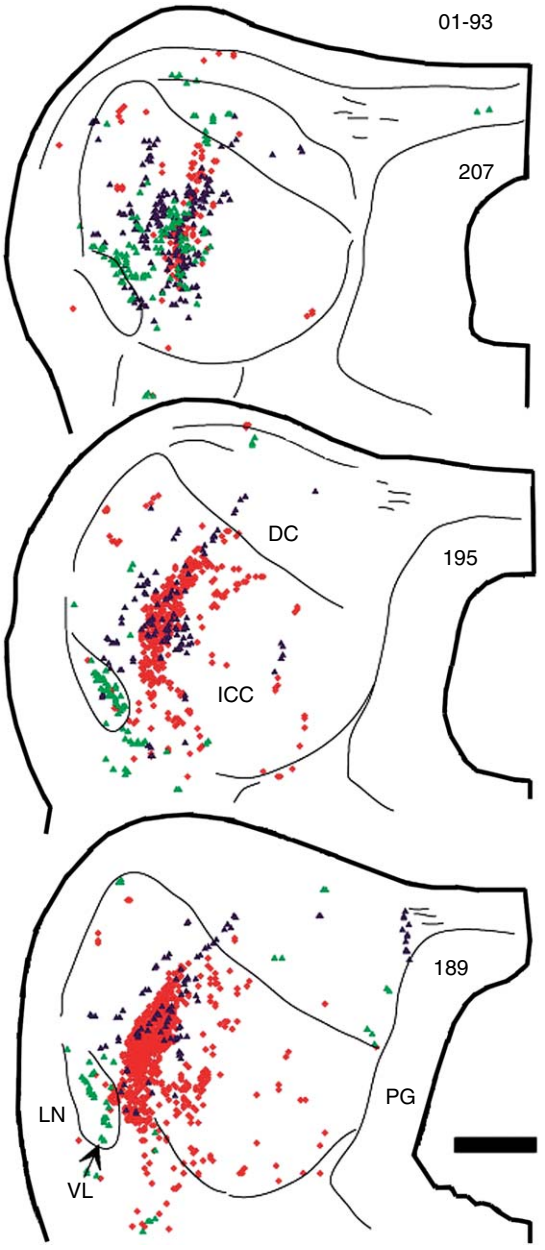

Figure 12 Frontal sections through the left inferior colliculus (IC) of the cat to compare the distribution of anterograde label from the medial superior olive (MSO; red), contralateral lateral superior olive (LSO; green) and ipsilateral LSO (blue). Sections are arranged rostral to caudal from top to bottom. DC, dorsal cortex; ICc, central nucleus of the IC; LN, lateral nucleus; PG, periaqueductal gray; VL, ventrolateral nucleus. From Loftus W. C. *et al*. (2004).

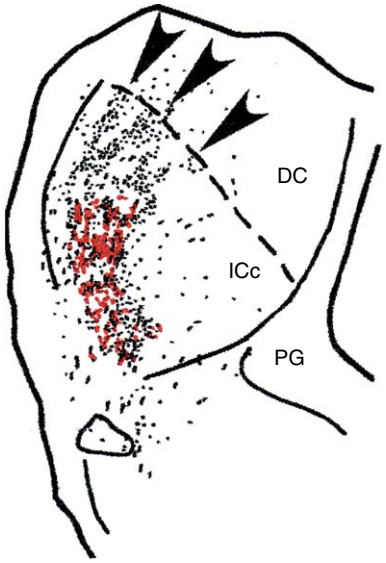

Figure 13 Frontal section through the left inferior colliculus (IC) of the cat showing the relation between anterograde transport from the contralateral lateral superior olive (LSO; red) and the contralateral dorsal cochlear nucleus (DCN) (black). Arrows point to a faint banded pattern in the central nucleus. DC, dorsal cortex; ICc, central nucleus of the IC; PG, periaqueductal gray.

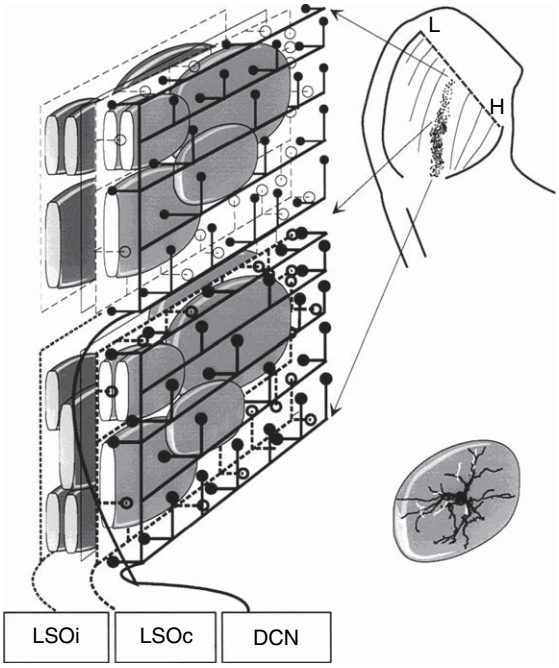

Figure 14 Model of functional zones or modules within a fibrodendritic lamina based on patterns of termination of axons from the dorsal cochlear nucleus (DCN), ipsilateral lateral superior olive (LSOi), and contralateral lateral superior olive (LSOc). The inset at the top right shows the location of the lamina that contains label within the tonotopic organization of the inferior colliculus. The small inset at the lower right shows a disk-shaped cell and its dendritic tree surrounded by a gray disk. Similar disks are used in the model to indicate the dendritic fields of individual disk-shaped neurons. The DCN axons terminate on both the dorsal and ventral parts of the lamina, but the LSO axons terminate only on the ventral part. The input from the contralateral LSO is mainly concentrated on one side of the lamina and that from the LSOi on the other side. L, low frequency; H, high frequency. From Oliver, D. L., Beckius, G. E., Bishop, D. C., and Kuwada, S. 1997. Simultaneous anterograde labeling of axonal layers from lateral superior olive and dorsal cochlear nucleus in the inferior colliculus of cat. J. Comp. Neurol. 382, 215–229.

from both sources interacting more ventrally except in a few small patches where only one input was present. In this model (Figure 14), afferents from the ipsilateral LSO are shown terminating on one side of the lamina and afferents from the contralateral LSO and DCN on the other side. The functional consequences of such a modular arrangement are unknown.

It should be kept in mind that all of the studies of this type conducted to date have examined the relationship between only two or, at most, three inputs to the IC. Given the large number of inputs that all project to the IC in a banded pattern with approximately the same spatial frequency, there must be considerable overlap among the bands from different sources as well as overlap between banded and nonbanded afferents.

3.42.5 Relation with Intrinsic Connections

The IC not only receives projections from outside sources; it also has an extensive system of intrinsic projections. Oliver D. L. *et al.* (1991) used intracellular injection of IC neurons in the cat to show that axons of IC neurons make local connections, and that at least some of them send branches both locally and to the brachium of the IC. The intrinsic projections appear to parallel the ascending projections (Saldana, E. and Merchan, M. A., 1992) as well as the crossed projections from the opposite IC (Malmierca, M. S. *et al.*, 1995). The intrinsic projections are confined to an isofrequency lamina as defined electrophysiologically, and the bulk of the projections ascend from ventrolateral to dorsomedial (Miller, K. E. *et al.*, 2005), creating a cascaded system of projections that includes progressively more multisynaptic inputs moving dorsomedially (Figure 15). Such a system would be ideally suited to create delay lines for processing temporal patterns of

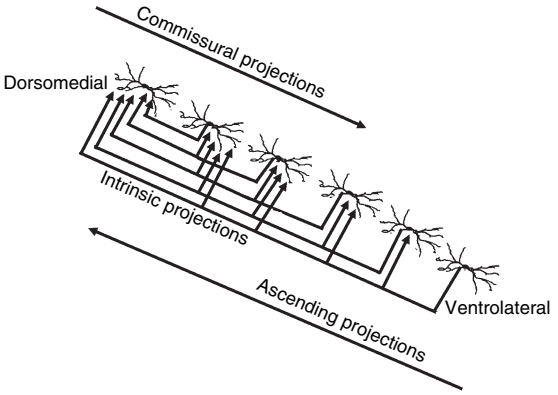

Figure 15 Schematic diagram to illustrate cascaded pattern of intrinsic projections within an isofrequency lamina of the inferior colliculus (IC). Neurons in the ventrolateral part of the lamina project to those located more dorsomedially. As a result, neurons in the dorsomedial part of the lamina have the opportunity to receive both direct and multisynaptic inputs from their more ventral counterparts. There is also opportunity for intrinsic inputs to converge with ascending inputs as well as descending and commissural inputs.

sound. The intrinsic inputs provide glutamatergic excitation (Saint Marie, R. L., 1996), and may also contain a GABAergic component (Fremouw, T. *et al.*, 1999). Because each fibrodendritic lamina has a system of intrinsic projections, there is ample opportunity for interaction of intrinsic inputs with ascending and descending inputs at every point within the lamina.

3.42.6 Biochemical Gradients

The IC receives both GABAergic and glycinergic inhibitory inputs. Because the only known sources of glycinergic input are in the lower brainstem pathways, particularly the SOC and NLL, it is not surprising that immunoreactivity for glycine and glycine receptors follows a pattern in which density is greatest ventrolaterally and lowest dorsomedially (Winer, J. A. *et al.*, 1995; Fubara, B. M. *et al.*, 1996; Casseday, J. H. *et al.*, 2003). However, instead of a continuous gradient, glycine and glycine receptor reactivity peaks in a crescent-shaped area just interior to the ventrolateral edge of the IC (Figure 16). The distribution of GABA immunoreactivity and $GABA_A$ receptors is the mirror image of the glycine distribution, with the lowest levels found in the crescent-shaped area that has the highest level of glycine (Winer, J. A. *et al.*, 1995; Casseday, J. H. *et al.*, 2003; Figure 16). $GABA_B$ receptors are most highly

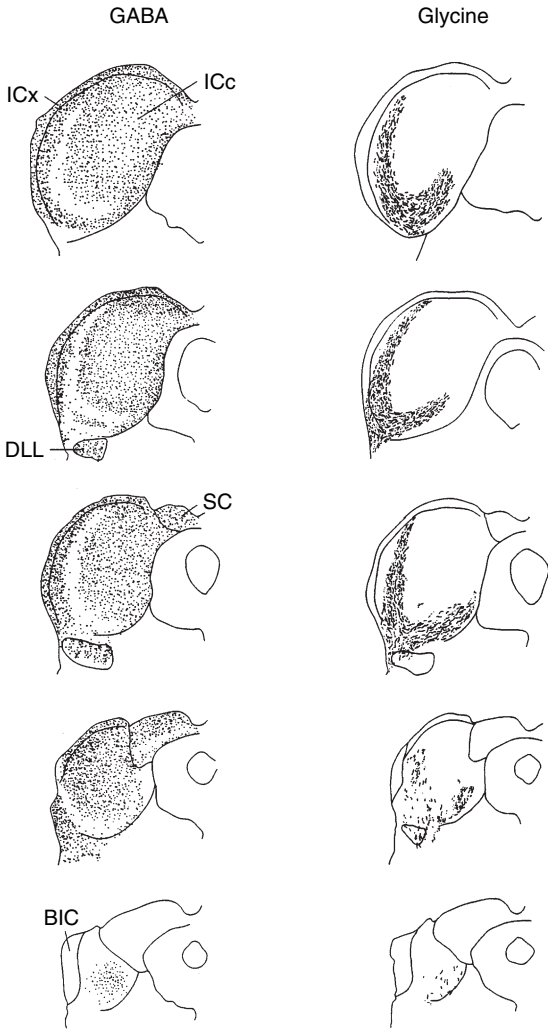

Figure 16 Distribution of immunoreactivity for gamma-aminobutyric acid (GABA; left column) and glycine (right column) in frontal sections through the left inferior colliculus (IC) of the big brown bat, *Eptesicus fuscus*. BIC, brachium of the IC; DLL, dorsal nucleus of the lateral lemniscus; ICc, central nucleus of the IC; ICx, external nucleus of the IC; SC, superior colliculus. From Casseday, J. H., Fremouw, T., and Covey, E. 2002. The Inferior Colliculus: Hub of the Auditory System. In: Springer Handbook of Auditory Research, Volume 15, Integrative Functions in the Mammalian Auditory Pathway (eds. D. Oertel, A. N. Popper, and R. R. Fay), pp. 238–318. Newyork: Springer.

expressed in the dorsomedial region of the IC where the DCN projection system terminates most densely (Fubara, B. M. *et al.*, 1996).

Serotonin has already been mentioned as being distributed in a pattern that corresponds to the DCN system gradient. Acetylcholine is also present in the IC, but its source is not entirely clear. Both of these neurotransmitters, when applied iontophoretically to

IC neurons during presentation of auditory stimuli, have effects that vary both quantitatively and qualitatively from one cell to another, suppressing responses in some and enhancing them in others (Farley, G. R. *et al.*, 1983; Habbicht, H. and Vater, M., 1996; Hurley, L. M. and Pollak, G. D., 1999). Serotonin has also been reported to change the subset of species-specific calls to which bat IC neurons responded (Hurley, L. M. and Pollak, G. D., 2005). Because of the mixed effects of the modulatory neurotransmitters, is likely that their effect depends on the other inputs that the neuron receives and on its intrinsic properties.

3.42.7 Evidence for Functional Gradients

It is clear from the anatomical evidence that there are multiple direct and indirect excitatory, inhibitory, and modulatory pathways to the IC. The multiple inputs provide different latencies, discharge patterns, tuning, thresholds, and binaural characteristics. Some subset of these pathways converge at every point throughout the IC, so there is ample opportunity for interaction of delayed and undelayed responses through direct and multisynaptic pathways, including intrinsic connections within the fibrodendritic laminae. The basic mechanisms through which multiple synaptic inputs interact have been described and reviewed elsewhere (e.g., Covey, E. *et al.*, 1996; Covey, E. and Casseday, J. H., 1998; 1999; Covey, E., 2004; Covey, E. and Faure, P. A., 2005). Because most of the inputs to the IC are not spatially homogeneous, but rather take the form of gradients, it might be expected that functional properties would vary continuously across the extent of the IC. There is some electrophysiological evidence suggesting that this is indeed the case.

There are at least a few studies that show evidence for gradients in a number of different response properties in the IC. Some of these gradients are consistent with the dorsomedial-to-ventrolateral pattern of the VCN and DCN systems, and others are not. Those that are generally consistent include discharge pattern, response latency, selectivity to modulation rate, selectivity for complex stimuli, stimulus-specific adaptation, and novelty responses.

In the mouse the proportion of transient responses is high in the dorsal part of the IC, decreasing ventrally (Reetz, G. and Ehret, G., 1999). These findings suggest that there is a stronger influence of inhibition dorsally than ventrally, or at least inhibition that would affect the later part of the response. Response latencies of IC neurons cover a broad range, from about 3 ms to more than 50 ms, and there are several studies in cats and bats that indicate that latencies are roughly organized in a dorsal-to-ventral gradient, with the longest latencies dorsally (Langner, G. 1992; Park, T. J. and Pollak, G. D., 1993; Hattori, T. and Suga, N., 1997). It might be supposed that convergence of excitatory and inhibitory inputs would lengthen latency, but blocking GABAergic and glycinergic inhibition has little effect on IC neurons' latencies (Fuzessery, Z. M. *et al.*, 2003). Even in cases where blocking inhibition causes latency to shorten, the amount of shortening is much less than would be required to produce the range of latencies seen in the IC (Casseday, J. H. *et al.*, 2000). All of these data are consistent with the idea that cascaded feedforward excitatory projections of the type seen in both the intrinsic and extrinsic projections to the IC may be the primary mechanism for progressively lengthening latencies dorsally in the IC without a need for inhibition, and for setting up delay lines that could participate in further processing of complex sounds (Miller, K. E. *et al.*, 2005).

Some IC neurons are selective for the rate of sinusoidal amplitude modulation (SAM). There is evidence in both cats and chinchillas to suggest that that there is a topographic distribution of best modulation frequencies with neurons selective for lower rates located dorsomedially and those selective for higher rates ventromedially (Schreiner, C. E. and Langner, G., 1988; Langner, G. *et al.*, 2002), again consistent with the gradients that have been described.

Moving from ventrolateral to dorsomedial an increasing proportion of neurons are selective for complex types of stimuli. For example, neurons that respond selectively to sinusoidal frequency modulations (SFM) are found mainly in the rostral and dorsal part of the IC (Casseday, J. H. *et al.*, 1997). Neurons in the dorsomedial part of the IC in the rat are more likely to show pronounced stimulus-specific adaptation and selective responses to novel stimuli (Covey, E. *et al.*, 2003).

Response–property gradients that do not directly map onto the gradients of the VCN–DCN systems include shape of neurons' frequency–response areas (Ehret, G. *et al.*, 2003). These authors report that in the mouse, the narrowest frequency–response areas are located in the central part of the IC, with broader ones more toward the outside. A similar center-outward gradient has been found in the mouse IC for frequency sweep speed and sweep direction, with selectivity for slow speeds and downward sweeps

most common in the centre of a lamina and high speeds and upward sweeps more common toward the outer edges (Hage, S. R. and Ehret, G., 2003). For response properties that follow a center-outward gradient, it may be that the center property reflects the greatest degree of convergence of the two main gradients, and the properties observed at either extreme may be characteristic of one system operating in isolation.

3.42.8 Summary

Figure 17 is a summary of the major anatomical gradient systems within the IC. The VCN–DCN gradient systems and the intrinsic projections are approximately orthogonal to the tonotopic progression, shown as an arrow from dorsolateral to ventromedial. The VCN system and DCN system provide opposing gradients in density of projections from the sources that contribute to them. At every point within the IC there is an opportunity for inputs from multiple sources to converge, and there is some evidence that at least the binaural inputs to a point along a lamina may be organized into functional domains in which one or another input predominates within a specific part of the lamina. There is evidence that at least some response properties are organized in ways that reflect the gradient structure within the IC. Given the large number of inputs to the IC, the high degree of overlap, and the complexity of the patterns of termination from different sources, it is not surprising that the IC contains multiple functional gradients, functional zones within the gradients, and other organizations of response properties, many of which remain to be investigated.

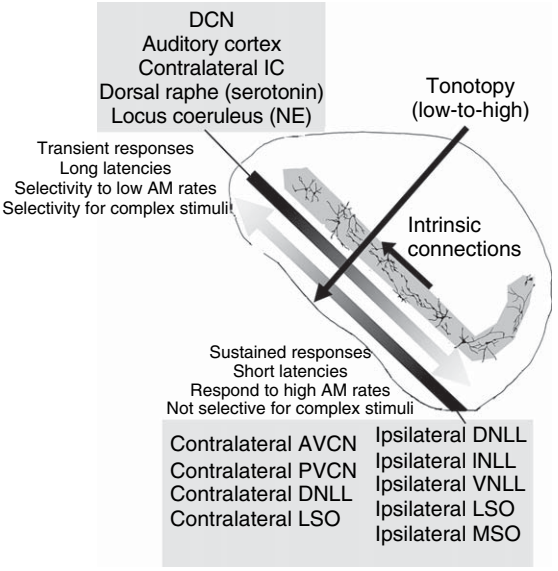

Figure 17 Summary diagram showing the two principal gradient systems within the inferior colliculus (IC) as they relate to the tonotopic organization (arrow showing tonotopy progressing from low at the dorsolateral edge to high at the ventromedial edge). AM, amplitude modulation; AVCN, anteroventral cochlear nucleus; DCN, dorsal cochlear nucleus; DNLL, dorsal nucleus of the lateral lemniscus; INLL, intermediate nucleus of the lateral lemniscus; LSO, lateral superior olive; MSO, medial superior olive; NE, norepinephrine; PVCN, posteroventral cochlear nucleus.

Glossary

afferent Movement toward a central area. Refers to neural projections going toward a particular structure.
binaural Relating to both ears.
contralateral The opposite side.
dorsal A position of an anatomical structure that is more toward the back or top in comparison to some other anatomical structure.
echolocation Method of sensory perception in which a bat or cetacean sends out a sound and uses the returning echo to orient, avoid obstacles, find food, and communicate.
ipsilateral The same side.
lateral A position that is farther from the midline of the brain.
medial A position that is closer to the midline of the brain.
monaural Relating to one ear.
spectral Frequency.
tonotopy Organization of frequency representation in a systematic manner.
ventral A position of an anatomical structure that is more toward the belly or bottom in comparison to some other anatomical structure.

3.43.1 Introduction

In between the cochlear nucleus and the inferior colliculus (IC) lies a complex set of auditory cell groups, the nuclei of the lateral lemniscus (NLL). While numerous physiological and anatomical studies have been conducted on the cochlear nucleus and the IC, the role of the NLL in detecting, localizing, and recognizing biologically relevant sounds is just beginning to emerge. What is clear, however, is that the NLL can be divided into two distinct functional systems based on the sources of afferent input and the characteristics of neural responses found in different nuclei. One functional system is part of the binaural pathways and includes the dorsal nucleus of the lateral lemniscus (DNLL). The second functional system is part of the monaural pathways and includes the intermediate nucleus of the lateral lemniscus (INLL) and the ventral nucleus of the lateral lemniscus (VNLL). The goal of this chapter is to review the characteristics of neural processing in both functional systems to better understand the role of the NLL in processing biologically relevant sounds in mammals.

3.43.2 Structure of the Nuclei of the Lateral Lemniscus

The NLL are groups of cell bodies that lie just ventral to the IC. The separation of the cell groups is highly variable across species such that in some species (e.g., rats) two groups of cell bodies are identified, whereas in other species (e.g., bats, cats, and guinea-pigs) four groups of cell bodies can be

identified. In all species, the dorsal group of cells is referred to as the DNLL. The DNLL consists of mostly fusiform cells that form clusters between dense bands of fibers in the lateral lemniscus; the fiber bundle that ascends to the IC (Figure 1). The DNLL is part of the binaural pathways as it receives afferent input from both the ipsilateral and contralateral lateral superior olivary (LSO) nucleus and from the ipsilateral medial superior olivary (MSO) nucleus (Glendenning, K. K. *et al.*, 1981); nuclei that are involved in processing interaural level differences and interaural timing differences, respectively. Electrophysiological recordings have also shown that most neurons in the DNLL are binaural (Brugge, J. F. *et al.*, 1970; Covey, E., 1993; Bajo, V. M. *et al.*, 1998). The structure and organization of the DNLL is similar across mammalian species, suggesting this is an evolutionarily conserved nucleus.

In contrast, the structure and organization of the ventral group of cell bodies is highly variable across species, possibly suggesting different sound processing needs based on different species' interactions with their environments. The ventral groups of cells are often lumped together and referred to as the VNLL or the ventral complex of the lateral lemniscus (VCLL). In this chapter, however, we will use the nomenclature derived from species (bats, cats, and guinea-pigs) in which four cell groups can be distinguished. The most dorsal group, the INLL, contains multipolar cells (guinea-pigs; Schofield, B. R. and Cant, N. B., 1997) or elongate cells (bats; Zook, J. M. and Casseday, J. H., 1982) with dendrites tending to lie mediolaterally and perpendicular to the passing lemniscal fibers. The INLL in echolocating bats tends to be very large, and in frontal sections it has a triangular outline that protrudes laterally (Figure 1(a)). This is quite distinct when compared to other species such as mouse (compare Figures 1(a) and 1(b)). It seems likely that the INLL plays an important role in the processing of echolocation signals.

Ventral to the INLL reside three distinct regions of the VNLL. Differences exist between bats and other species in which these regions are apparent. In the guinea-pig, the dorsal portion of the VNLL (VNLLd) contains mainly multipolar cells with dendrites oriented perpendicular to the lemniscal fibers. The cells in VNLLd are scattered throughout the region in no particular organization (Schofield, B. R. and Cant, N. B., 1997). More ventrally lies the ventral division of the VNLL (VNLLv). The VNLLv contains a variety of cell types including multipolar and giant cells. Most distinctive are the spherical neurons that resemble spherical bushy cells found in the

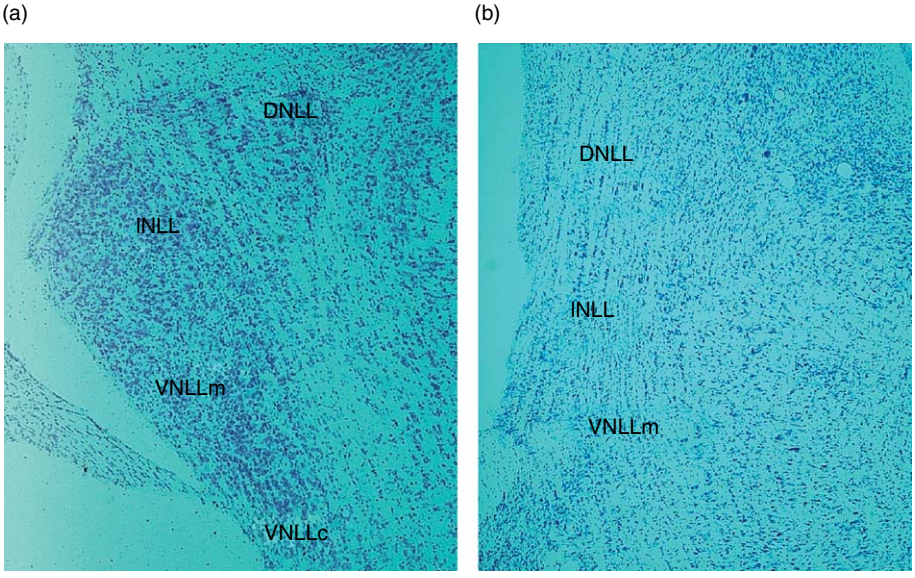

Figure 1 Photomicrographs of the NLL. Nissl staining illustrates the different nuclei. (a) Four distinct nuclei are apparent in the mustached bat. The columnar organization of VNLLc is distinct from the organization of cells in the other nuclei. The striated pattern of cell clustering in the DNLL is due to the passage of lemniscal fibers traveling to the IC. (b) Dorsal and ventral nuclei of the lateral lemniscus in the mouse are more typical of mammalian species. Divisions between nuclei are not as apparent as in the mustached bat.

cochlear nucleus. These neurons receive afferent input through endbulbs from octopus cells in the posteroventral cochlear nucleus (Vater, M. and Feng, A. S., 1990; Schofield, B. R., 1995; Adams, J. C., 1997). Finally, the VNLLa is a more anterior cluster of cells within the VNLL that contains multipolar cells. The distinctive feature of this region compared to the VNLLd is that the dendrites are oriented parallel to the lemniscal fibers.

In echolocating bats, the VNLL is hypertrophied and has a highly organized structure consisting of a columnar region (VNLLc) and a multipolar region (VNLLm). In the mustached bat (*Pteronotus parnellii*), the ventral part of the nucleus contains small, multipolar cells that are organized in densely packed columns, providing a distinct columnar appearance that is strikingly different compared to the dorsal part of the nucleus (Figure 1(a)). The VNLLm contains multipolar cells that have a variety of shapes and no distinct organization (Zook, J. M. and Casseday, J. H., 1982). The locations of the VNLLc and VNLLm in the big brown bat (*Eptesicus fuscus*) are reversed with the VNLLc dorsal to the VNLLm (Covey, E. and Casseday, J. H. 1986). The cells in the VNLLc are spherical bushy cells that receive their inputs through endbulbs and thus resemble neurons in the VNLLv of other species (Covey, E. and Casseday, J. H., 1986; Vater, M. *et al*., 1997).

Although different species show differing levels of separation and organization of the INLL and VNLL, in all species these regions receive monaural input, predominantly from the cochlear nucleus. Afferent input from monaural nuclei in the brainstem makes the INLL and VNLL part of the monaural ascending auditory pathways, and consequently the monaural NLL. In subsequent sections of this chapter, the function of the NLL is discussed in terms of the binaural and monaural functional systems.

3.43.3 Role of the Dorsal Nucleus of the Lateral Lemniscus in Binaural Hearing

Connectional, immunocytochemical, and electrophysiological studies all provide evidence for the DNLL playing an important role in binaural processing and sound localization. Neurons in the DNLL receive projections from the LSO and MSO (Glendenning, K. K. *et al*., 1981), utilize gamma-aminobutyric acid (GABA), and are inhibitory (Adams, J. C. *et al*., 1984; Vater, M. *et al*., 1997); they are also sensitive to variations in interaural intensity and/or time differences (Brugge, J. F. *et al*., 1970; Covey, E., 1993; Bajo, V. M. *et al*., 1998), which are the two major binaural cues for sound localization. Binaural responses of DNLL neurons are characterized by excitation to a contralateral sound source and inhibition to an ipsilateral sound source, creating what is referred to as an E/I response.

Neurons in the DNLL respond with sustained or transient discharge patterns. In the rat, the most common discharge pattern is a strong phasic response at the stimulus onset followed by a sustained response throughout the duration of the stimulus and an offset inhibition (Bajo, V. M. *et al*., 1998). In the DNLL of big brown bats, equal numbers of transient and sustained responses occur (Covey, E., 1993). The sustained responses have features similar to those seen in LSO neurons and most likely reflect LSO input. The transient discharge patterns likely reflect MSO input. Thus, the discharge patterns of DNLL neurons mainly reflect their inputs rather than their own membrane properties.

No clear pattern of tonotopic organization in the DNLL has resulted from physiological or anatomical studies. Neurons with similar best frequencies seem to cluster together in both bats (Covey, E. 1993) and rats (Bajo, V. M. *et al*., 1998). In rats, neurons that are responsive to high frequencies cluster in the dorsal and ventral parts of the DNLL, with neurons responsive to low frequencies located in the middle.

If DNLL neurons receive their sensitivity to interaural timing or interaural intensity differences from the MSO and LSO, and the MSO and LSO impart similar response properties directly onto IC neurons, what role does the DNLL play in binaural processing? Interestingly, the EI properties of some neurons in the IC are modified or created at the level of the IC (Faingold, C. L. *et al*., 1993). The DNLL sends bilateral inhibitory projections to the IC, and, in particular, the contralateral projection creates a novel response property in the IC that does not occur in lower binaural nuclei or in cells in the IC that do not receive a DNLL projection (Burger, R. M. and Pollak, G. D., 2001). One of the consequences of the contralateral inhibitory input is the creation of IC neurons that can process the location of a moving sound source or multiple sound sources located in different regions of space.

The inhibition elicited by ipsilateral stimulation in DNLL neurons often lasts for many milliseconds (Yang, L. and Pollak, G. D., 1998). Burger R. M. and Pollak G. D. (2001) showed that this persistent

inhibition in DNLL neurons causes normally suppressed binaural neurons in the IC to become responsive. Their argument is that if the DNLL neuron has persistent inhibition, the IC cell loses its ipsilaterally evoked inhibition and it consequently will respond to a second, or trailing, binaural sound to which it would not respond if that sound were presented alone. However, an additional consequence of this circuitry is that the sensitivity to the location of the trailing sound is reduced. These data suggest that the role of the DNLL is to change the interaural intensity sensitivity of IC cells to trailing sounds. The findings of Burger R. M. and Pollak G. D. (2001) correlate well with characteristics of the precedence effect. In the precedence effect, when two identical sounds are presented from speakers separated along the same plane in space and the second sound is slightly delayed from the first sound, the listener hears the trailing sound but cannot localize the sound (Litovsky, R.Y. *et al.*, 1999). The neural mechanism for the precedence effect may lie within the DNLL.

3.43.4 The Monaural Nuclei of the Lateral Lemniscus

3.43.4.1 General Features

In contrast to the DNLL, the INLL and VNLL have typically been considered monaural nuclei. While there is no evidence to the contrary for the INLL, the view of the VNLL as strictly monaural is slightly more controversial. While all studies in the big brown bat show neurons in both the VNLLm and VNLLc to be excited by sound at the contralateral ear and unaffected by sound at the ipsilateral ear (Covey, E. and Casseday, J. H., 1991), recent studies in the unanesthetized rabbit suggest that many neurons in the VNLLm are sensitive to interaural temporal disparities (ITDs); a major cue for sound localization (Batra, R. and Fitzpatrick, D. C., 2002). These neurons, however, respond differently than the majority of ITD sensitive cells found in traditional binaural nuclei in the auditory system, suggesting that their function may be slightly different. First, these neurons in VNLLm respond to the onset of the sound, whereas other ITD-sensitive neurons respond in a sustained manner. Second, the VNLLm neurons do not respond to dynamically changing ITDs, whereas ITD-sensitive neurons in other auditory nuclei respond vigorously to this type of stimulus. These differences suggest that the ITD-sensitive neurons in the VNLLm of unanesthetized rabbits may be specialized for detecting transient changes in ITDs (Batra, R. and Fitzpatrick, D. C., 2002). These preliminary data are intriguing and may alter the way the VNLL is viewed functionally, but it remains to be determined if neurons in the VNLL of other species are involved in any type of binaural processing or if they are strictly monaural as in echolocating bats.

Whether the monaural nuclei of the NLL exhibit a tonotopic organization is a debatable question. Some level of tonotopy has been reported in the INLL of big brown bats (Covey, E. and Casseday, J. H., 1991) and mustached bats (unpublished observations). The VNLLm of big brown bats shows a tonotopic organization, where high frequencies are represented in the center of the nucleus and lower frequencies around the core (Covey, E. and Casseday, J. H., 1991). These data fit well with the findings from anatomical studies in the rat in which retrograde tracer deposits were made in specific frequency laminae in the IC and patterns of retrogradely labeled cells in the VNLL showed a concentric organization with respect to the tonotopy in the IC (Merchan, M. A. and Berbel, P., 1996). In cats, patterns of retrogradely labeled cells in the VNLL are patchy; labeled cells after high-frequency deposits in the IC appear more laterally and more medially after low-frequency deposits (Malmierca, M. S. *et al.*, 1998). Thus, in cats there seems to be a mediolateral gradient of projections from the VNLL to the IC. However, this conclusion assumes that the projections from the VNLL to the IC are in fact tonotopic. As the IC is the first nucleus in the ascending pathway to show spectral integration properties suggesting that some cells receive nontonotopic projections from brainstem nuclei (Wenstrup, J. J. *et al.*, 1999; Portfors, C. V. and Felix, R. A., II, 2005), it is possible that the frequency response of the VNLL neurons does not match the frequency representation of the IC targets. Electrophysiological evidence of tonotopy in the VNLL in cats is lacking (Aitkin, L. M. *et al.*, 1970), questioning the interpretation of the anatomical studies.

3.43.4.2 Role of the Nuclei of the Lateral Lemniscus in Frequency Integration

The role the monaural nuclei play in processing sounds with complex frequency and temporal structures is unclear, but recent studies provide evidence as to their role in shaping response properties in the IC. Integration of spectral and temporal elements in complex sounds is essential for appropriate

representation of these sounds. Spectral integration properties such as tuning to multiple frequencies and facilitatory or inhibitory responses to the combination of two distinctly different frequency elements (combination sensitivity) occur in the IC of bats and mice (Portfors, C. V. and Wenstrup, J. J., 1999; Portfors, C. V. and Felix, R. A., II, 2005). Tuning to multiple frequencies, at least in the mustached bat, occurs to a small extent (<10% of neurons) in the NLL and VNLL. In addition, approximately 25% of neurons in the INLL show combination-sensitive response properties with most being inhibitory (Portfors, C. V. and Wenstrup, J. J., 2001). Complex responses in the INLL and VNLL occur to a far lesser extent than in the IC of the mustached bat (Portfors, C. V. and Wenstrup, J. J., 1999; 2002). This suggests that the IC plays a more substantial role in spectral integration of complex sounds than the NLL.

However, the inhibitory combination-sensitive responses in the INLL may shape responses to complex sounds in the IC. In the mustached bat, the IC contains neurons that are specialized for encoding target distance information (Portfors, C. V. and Wenstrup, J. J., 1999). These facilitatory FM-FM neurons respond to the combination of the first harmonic frequency-modulated (FM) sweep in the bat's emitted call followed by a higher FM harmonic in the returning echo. Each neuron responds best to a particular delay between the emitted call and the returning echo. Neurons that respond best to delays longer than 20 ms show a strong period of inhibition that precedes the facilitatory response. Portfors C. V. and Wenstrup J. J. (2001) found FM-FM neurons in the INLL that were inhibitory rather than facilitatory and suggested that these inhibitory FM-FM neurons could provide a dominant excitatory input to the long best delay neurons in the IC to create the prefacilitation inhibition. Support for this idea comes from a recent study by Nataraj K. and Wenstrup J. J. (2006), who found that 59% of neurons in the IC showed early inhibition that preceded facilitation and this inhibition was not eliminated with the application of bicuculline (GABAA antagonist) or strychnine (glycine antagonist). These data suggest that the inhibition resulting from the combination of two distinctly different frequency elements arises below the IC, possibly in the INLL. The key experiment to provide convincing evidence is to eliminate the combination-sensitive inhibitory responses in the INLL and test whether this eliminates the early inhibition in facilitatory neurons in the IC.

3.43.4.3 Role of the Monaural Nuclei in Temporal Coding

Many response characteristics of neurons in the INLL and VNLL make them well suited to encode temporal information in sounds: little spontaneous activity, broad frequency tuning, and short integration times (Covey, E. and Casseday, J. H., 1991). Moreover, differences in response characteristics between INLL, VNLLm, and VNLLc in echolocating bats suggest that INLL and VNLLm are involved in encoding temporal features of an ongoing sound, whereas VNLLc is involved in encoding information related to the onset of the sound (Covey, E. and Casseday, J. H., 1991).

Fundamental differences in frequency tuning, discharge pattern, and variability of first spike latency are seen in VNLLc compared to VNLLm or INLL in big brown bats (Covey, E. and Casseday, J. H., 1991). Tuning curves in VNLLc are much broader. This is important because a high level of temporal precision is gained at the expense of frequency precision. Thus, broad frequency tuning in VNLLc neurons suggests that they have better temporal precision. In addition, all neurons in VNLLc show a phasic onset discharge pattern with constant latency, whereas neurons in INLL and VNLLm show either phasic onset with variable latency or sustained discharge patterns. The ranges of latencies also differ between nuclei. Latencies tend to be shortest in VNLLc and longest in INLL (Covey, E. and Casseday, J. H., 1991; Portfors, C. V. and Wenstrup, J. J., 2001).

Neurons in the VNLLc are of special interest because of their ability to signal the onset of the sound very precisely. These neurons use the inhibitory neurotransmitter glycine (Vater, M. *et al.*, 1997) and thus send a precisely timed inhibitory input to the IC. This precise inhibitory input has been suggested to possibly play a role in resetting IC neurons to prepare them for a subsequent signal or in encoding sound duration in the IC (Casseday, J. H. *et al.*, 2002). Regardless, it is clear that neurons in the VNLLc encode very different aspects of sound than neurons in the INLL, VNLLm, and DNLL.

3.43.5 Concluding Remarks

The NLL represent a set of structures in the auditory brainstem that dramatically influence how the IC processes sound. The binaural and monaural functional systems of the NLL play unique and important

roles in transforming inputs from the lower brainstem and modifying responses in the IC. This chapter has only touched the surface on the functional importance of the NLL, but it should be clear that many more experiments are waiting to be done to better understand the NLL. For example, Bauer E. E. *et al.* (2002) recently showed that neurons in the DNLL do not show any specializations for encoding species-specific vocalizations, yet responses to species-specific vocalizations have not been tested in the monaural nuclei of the NLL. Based on temporal response properties and spectral integration properties in the INLL and VNLL, the likelihood of these nuclei showing specializations for encoding species-specific vocalizations seems higher than in the DNLL. In addition, the majority of physiological studies on the NLL have been conducted in bats. As the INLL and VNLL in bats are hypertrophied and may have evolved certain response features for echolocation behaviors, it is important to understand response characteristics in the NLL of a variety of species. Comparisons across species are vital for understanding the evolution of species-specific neural mechanisms versus mechanisms that are common across all species.

Glossary

interaural level difference (ILD) An important spatial cue for auditory stimuli derived from differences in sound amplitude at the two ears.

interaural timing difference (ITD) An important cue for the horizontal location of an auditory stimulus derived from relative timing differences between a sound reaching the near and far ear.

optic tectum The nonmammalian homolog to the superior colliculus, which is involved in stimulus detection and gaze control.

receptive field The area in a particular sensory space in which a neuron will respond to stimuli.

topographic A systematic anatomical arrangement, often referring to neural representations that emulate the original sensory space.

3.44.1 Introduction

Experience shapes behavior and the neural circuits that underlie behavior throughout an animal's life. In many neural circuits, the shaping influence of experience is particularly strong during early periods in development. Such sensitive periods are hallmarks of the circuits that underlie binocular vision, language acquisition, social behavior, and song learning in birds (Hensch, T. K., 2004). The barn owl midbrain auditory localization pathway also passes through a sensitive period during which visual experience calibrates auditory localization behavior, allowing individual experience to shape the relationship between auditory cues and the locations of auditory stimuli in visual space (Brainard, M. S. and Knudsen, E. I., 1998).

Early studies documented a dramatic decline in the plasticity of the auditory localization pathway as owls approached adulthood. Recent experiments, however, have demonstrated a far greater capacity for plasticity in adult owls than was previously thought. This plasticity likely maintains accurate auditory localization in the face of aging processes that alter the neural coding of binaural signals. The conditions necessary to induce plasticity in adult owls are more specific than those required in juveniles. This chapter reviews how sensory experience guides the development of aligned maps of auditory and visual space in the midbrain of the barn owl, describes how the capacity to adapt changes throughout an animal's life, and discusses ways to increase plasticity in adult owls through specific training techniques.

3.44.2 Synthesis of the Auditory Space Map

Audition and vision provide complementary information about the nature of stimuli. Sounds provide an animal with information that is not visually

accessible while vision provides accurate and precise information about the shape, size, and location of an object. Integrating auditory and visual information improves both the speed and accuracy with which stimuli are detected (Stein, B. E. and Meredith, M. A., 1993). As nocturnal predators, barn owls rely heavily on both of these senses to survive.

While information about the location of a visual stimulus is available immediately in the retina, the location of an auditory stimulus must be inferred from a variety of monaural and binaural cues. The primary cues for the horizontal location of an auditory stimulus are small timing differences between sounds arriving at the near and far ears, called interaural timing differences (ITDs). Additional cues, such as the interaural level difference (ILD), are important indicators of both the horizontal and vertical locations of stimuli.

The auditory system measures auditory cues, such as ITD and ILD, and associates particular values of these cues with the appropriate locations in space (Gutfreund, Y. and Knudsen, E. I., 2004). The initial analysis of ITD and ILD cues are carried in frequency-specific channels. However, within the midbrain, at the level of the external nucleus of the inferior colliculus (ICX), these frequency specific channels combine information to yield a map of auditory space (Figure 1). This map of auditory space is then relayed to the optic tectum (OT), where auditory and visual inputs merge and receptive fields align to create a multimodal map of space (Gutfreund, Y. and Knudsen, E. I., 2004). A primary purpose of this multimodal space map is to orient the owl's gaze towards salient stimuli regardless of the sensory modality that detected the stimulus. The alignment of auditory and visual receptive fields in the OT also makes it possible to quantify auditory plasticity at any point in the space map by measuring the difference between the observed auditory tuning and the expected auditory tuning based on the location of the visual receptive field.

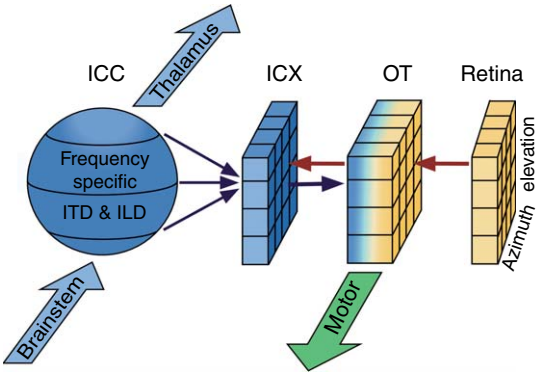

Figure 1 Sensory representations and processing in the barn owl midbrain. Auditory structures are shown in blue and visual structures are yellow. Frequency-specific interaural timing differences (ITDs) and interaural level difference (ILD) information is conveyed from brainstem nuclei to the central nucleus of the inferior colliculus (ICC). Spatial cues converge across ICC frequency laminas to form a single map of auditory space in the external nucleus of the inferior colliculus (ICX). This auditory map is then relayed forward to the optic tectum (OT) where it is aligned with a retinotopic map of visual space. Sensory activity, of either modality, within the deep layers of the OT triggers orienting head movements which bring the owl's gaze toward the location of the stimulus. A visually based spatial template projects from the OT back to the ICX. This pathway possesses many attributes necessary for instructing experience-dependent changes of auditory tuning within the ICX.

3.44.2.1 Visual Calibration of the Auditory Space Map

The first hint that the alignment of auditory and visual space maps in the OT might be guided by visual signals came from the observation that the auditory map magnifies frontal space in a manner that is predicted by the photoreceptor density in the retina, but is not predicted by properties of auditory spatial cues (Knudsen, E. I., 1982). Subsequently, the role of visual signals in calibrating auditory localization has been experimentally demonstrated in several species. For example, when owls are raised with horizontally displacing prismatic spectacles (prisms), the relationship between the locations of auditory stimuli and visual stimuli is offset by the magnitude of the prismatic displacement. Immediately after prisms are mounted on an owl, the owl's auditory orienting behavior is unchanged; however, this behavior fails to direct the animal's gaze to the source of an auditory stimulus. Over the course of several weeks, young owls recalibrate the relationship between auditory spatial cues and the locations in visual space that produce them such that they accurately fixate the source of the sound as seen through the prisms (Gutfreund, Y. and Knudsen, E. I., 1989). During this same period of time, the auditory spatial tuning of neurons in the OT changes in a manner that restores register of the auditory map with the prismatically displaced visual map (Figure 2). Axon growth, synapse formation, and changes in the gamma aminobutyric acid (GABA)ergic inhibition of native connections all contribute to the adaptive remodeling of the auditory space map (Feldman, D. E. and Knudsen, E. I., 1997; Zheng, W. and Knudsen, E. I., 1999; DeBello, W. M. *et al.*, 2001).

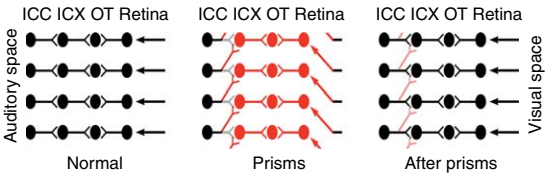

Figure 2 Anatomical changes associated with auditory plasticity. Normal: the native architecture for processing auditory and visual spatial information within the owl midbrain. Auditory spatial information is relayed from the central nucleus of the inferior colliculus (ICC) to the external nucleus of the inferior colliculus (ICX), where a map of space is formed. The space map in the ICX is then relayed to the optic tectum (OT) where it aligns with a map of visual space inherited from the retina. Prisms: the end result of prism-induced auditory plasticity. Prisms alter the horizontal trajectory of light hitting the retina, thereby shifting the visual map of space in the OT. In response to the altered visual space map, axonal growth and the formation of new synapses change the flow of auditory spatial information from the ICC to the ICX. These adaptive changes bring the auditory map of space back into alignment with the displaced visual map (red). The original anatomical projection from the ICC to the ICX remains, but the auditory responses it supports are suppressed by inhibition. After prisms: after prisms are removed the auditory space map returns to normal, however, the anatomical changes associated with prism adaptation remain (pink). This anatomical trace can be reactivated by experience in adulthood.

3.44.2.2 Instruction of the Auditory Space Map in the Inferior Colliculus

Prism-induced auditory plasticity is an example of supervised learning. While most prism experiments have focused on measuring auditory map plasticity in the OT, the ICX is the first nucleus in the midbrain auditory localization pathway to exhibit a shifted auditory space map. The auditory tuning of neurons in the lateral shell of the inferior colliculus (ICCls), one nucleus earlier in the pathway, is not affected by prism experience (Gutfreund, Y. and Knudsen, E. I., 2004). This finding raises two interesting questions. First, what is the source of instructive signals that guide auditory plasticity? Second, how does visual experience instruct auditory plasticity within a nucleus, the ICX, which is commonly regarded as a strictly auditory structure?

The instructive signal guiding auditory plasticity could either be a topographic template of visual space or it could simply indicate whether a particular head/eye movement was successful in foveating the source of an auditory stimulus. To distinguish between these two possibilities, Hyde P. S. and Knudsen E. I. (2001) raised owls with prisms that displaced only the representation of central visual space. If the instructive signal were a foveation-based signal, one would expect this manipulation to induce uniform plasticity across the entire auditory space map since all orienting movements must direct the optically displaced central gaze to the stimulus location. Alternatively, if the instructive signal were a topographic map of visual space, then one would expect this manipulation to induce plasticity only in the portion of the map that was displaced by prisms. The result was that only the auditory tuning of neurons corresponding to the prismatically displaced area of space was affected by prisms. Subsequently, the source of such a topographic instructive signal was identified as the OT: small lesions in the OT impeded auditory plasticity only in the portions of the ICX map that represented the same locations in space as lesioned in the OT (Hyde, P. S. and Knudsen, E. I., 2002).

Experiments have revealed a feedback projection from the OT to the ICX that meets all of the requirements necessary for an instructive signal (Hyde, P. S. and Knudsen, E. I., 2000; Luksch, H. *et al.*, 2000; Gutfreund, Y. *et al.*, 2002). These experiments provide two critical insights about the nature of this projection; (1) it is a point-to-point topographic projection from the OT to the ICX, and (2) it carries spatially selective visual signals that can be observed by blocking inhibition in the OT. These characteristics strongly suggest a role for this pathway in instructing adaptive auditory plasticity in the ICX. Characterizing the normal function of this potential instructive signal will be an exciting area of research.

3.44.2.3 Developmental Regulation of Map Plasticity

The plasticity of the auditory space map in the OT declines with age. This principle is illustrated by a set of experiments in which naïve owls were fitted with prisms at different ages. While prism experience led to nearly complete adaptive adjustments of the map in juvenile owls (meaning that the alignment of the auditory space map with the optically displaced visual space map was restored), the same prisms had little effect in adults (Brainard, M. S. and Knudsen, E. I., 1998). The decline in map plasticity occurs before owls are about 200 days old, which corresponds roughly to the age at which owls reach sexual maturity. Sensitive periods for auditory map development have also been described in the superior colliculus (mammalian homolog of the OT) of ferrets and guinea-pigs (King, A. J., 1999).

3.44.3 Manipulations that Increase Auditory Plasticity in Adults

The reduced plasticity observed in adult versus juvenile owls is not simply due to the same mechanisms operating more slowly in adults, since prolonging prism experience does not significantly increase adaptive plasticity. A number of factors could lead to the reduced plasticity in adult owls. For example, the system may be less plastic in adults; the signals that instruct auditory plasticity in juvenile owls may not be present, or are ignored, in adults; or the environmental and psychological factors required to induce plasticity may be more stringent in adults, and these conditions were not met in the early prism experiments. These possibilities are not mutually exclusive, and the experiments discussed below indicate that multiple factors regulate plasticity.

3.44.3.1 Training During the Juvenile Period

Adult plasticity is increased by learning during the juvenile period. When young owls are raised with prisms, they readily acquire a novel ITD map. After the prisms are removed, the auditory tuning in these owls returns to normal. Even though these owls express a functionally normal ITD map as adults, when exposed to the same prisms a second time they rapidly reacquire a shifted ITD map (Knudsen, E. I., 1998). The increased auditory plasticity in these adults is specific to the plasticity they expressed as juveniles: they are capable of adapting only to the prismatic shifts that they experienced as juveniles.

Prism adaptation physically changes the brain of young owls. The changes in ITD tuning observed in the ICX and OT are associated with an anatomical change in the axonal projection from the ICCls to the ICX. In prism-reared owls, this projection is significantly broader than in normal owls, and the broadened distribution of axon terminals in the ICX is skewed towards zones in which these terminals could support newly learned auditory responses (DeBello, W. M. *et al.*, 2001; Figure 2). Moreover, these acquired projections persist long after the prisms are removed, leaving an anatomical trace of the learning that could underlie the ability of adult owls to reacquire the alternative auditory map that was learned during the juvenile period (Linkenhoker, B. A. *et al.*, 2005; Figure 2). These results show that signals that instruct changes in auditory tuning continue to function, even though they often fail to affect auditory tuning in the adult owl.

3.44.3.2 Training in Small Increments

When adult owls are exposed to strong prisms (23° optical displacement), the auditory space map adjusts by less than 3°, even after 6 months of experience. In contrast, when owls are exposed to weak prisms (6° optical displacement), they acquire a full 6° shift of the auditory map within 3 weeks (Linkenhoker, B. A. and Knudsen, E. I., 2002). This adaptation to small prismatic shifts lays a foundation for subsequent adaptation to yet stronger prisms (Figure 3). When prismatic displacements are gradually introduced, owls eventually acquire dramatically shifted ITD maps to large (17–23°) prismatic displacements, displacements that have little effect on auditory tuning when introduced to adults as a single abrupt change in experience. Thus, a smaller difference between the desired and the existing auditory space map is more effective in altering the map of space in adult owls. Once owls have acquired a shifted ITD map through incremental training, they are able to reacquire the map in response to a single large displacement, indicating that incremental training increases the capacity for plasticity in this system.

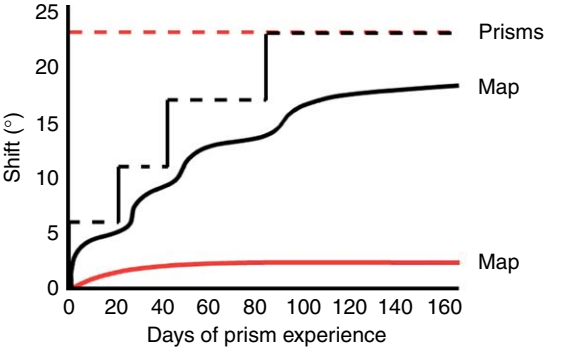

Figure 3 Incremental training increases auditory map plasticity. The ordinate represents both the prismatic shift of visual fields (Prisms; dashed lines), and the resulting shifts of the auditory space map (solid lines). Shifts in the auditory map were measured as the difference between the expected auditory tuning (based on nondisplaced visual tuning) and the observed auditory tuning. Auditory plasticity in adult owls is affected little by a single large (23°) prismatic displacement (red lines). In contrast, auditory tuning changes substantially in response to incremental increases in prismatic displacements. Black lines: adapted from Linkenhoker, B. A. and Knudsen, E. I. 2002. Incremental training increases the plasticity of the auditory space map in adult barn owls. Nature 419, 293–295.

3.44.3.3 Hunting Increases Map Plasticity

The midbrain auditory localization pathway has evolved in the context of specific types of experience. Hunting, in particular, is a crucial behavior that relies extensively on the optic tectum for directing an animal's gaze toward salient stimuli. In addition, hunting engages factors such as attention and arousal that are known to be important modulators of neural plasticity. However, in all prism experiments discussed so far, owls were not allowed to hunt live prey. Recent experiments have shown that allowing adult owls to hunt, while wearing prisms, induces five times more adaptive plasticity as compared to adult owls that are not allowed to hunt (Bergan, J. F. *et al*., 2005). One hypothesis is that experience with bimodal stimuli during periods of heightened attention and arousal underlies this effect. Another possibility is that not providing owls with the chance to perform instinctual behaviors induces a general depressed state which inhibits learning. While the mechanism by which exposure to hunting increases auditory map plasticity in adults is not yet known, it is clear that key environmental factors can have a dramatic influence on plasticity within the adult brain.

3.44.4 Conclusions

Auditory localization behavior and the underlying neural circuits are shaped by visual experience. Initially, it was thought that the influence of visual experience on auditory localization was restricted to a particular developmental window early in life. More recent experiments have shown that, although juveniles express greater plasticity than adults, adult owls maintain a substantial capacity for adaptive change. However, the experimental manipulations that elicit adaptive plasticity in adult owls are more sophisticated and reflect the kinds of experiences an adult owl might have naturally. For example, small changes in sensory experience are reminiscent of the effects of gradual aging on stimulus coding in the central auditory system, and hunting is of vital importance to an adult owl's survival. Through the growing understanding of important factors that modulate the capacity for plasticity throughout an animal's lifetime, we are becoming increasingly aware of the brain's astounding ability to acquire and maintain high performance by learning from experience.

Glossary

auditory core Those areas of auditory cortex at the first level of cortical processing. The core has the architectonic features of primary sensory cortex and distributes auditory information to other areas.

cortical area The larger functional subdivisions of cortex that are considered the organs of the cortex. They are distinguished by a unique set of anatomical and physiological features including a pattern of connections with other cortical areas and subcortical nuclei. Auditory and other sensory areas often have systematic representations of sensory receptors.

auditory belt A second level of cortical auditory processing in an array of eight proposed auditory areas surrounding the auditory core.

auditory parabelt A region of auditory cortex adjacent to the lateral auditory belt that receives inputs from belt areas and constitutes a third level of cortical processing.

dorsal and ventral streams Dosrsal core, belt, and parabelt regions are more densely interconnected with each other, as are ventral core, belt, and parabelt regions, forming the early stages of dorsal and ventral streams of auditory cortical processing The ventral stream appears to be more devoted to sound identification, while the dorsal stream is more devoted to sound localization.

3.45.1 Introduction

Auditory systems in mammals contain a large number of interconnected subcortical nuclei and cortical areas. The subcortical nuclei are thought to be highly similar across mammalian taxa (phylogenetic groups) but the subdivisions of auditory cortex vary. Thus, considerable processing of auditory stimuli occurs across five levels of nuclei in several parallel, interacting pathways before auditory cortex is reached (Figure 1).

At the level of cortex, all mammals appear to have one or more primary or primarylike auditory areas, a fringe or belt of a variable number of associated secondary areas, and perhaps one or two stages of further

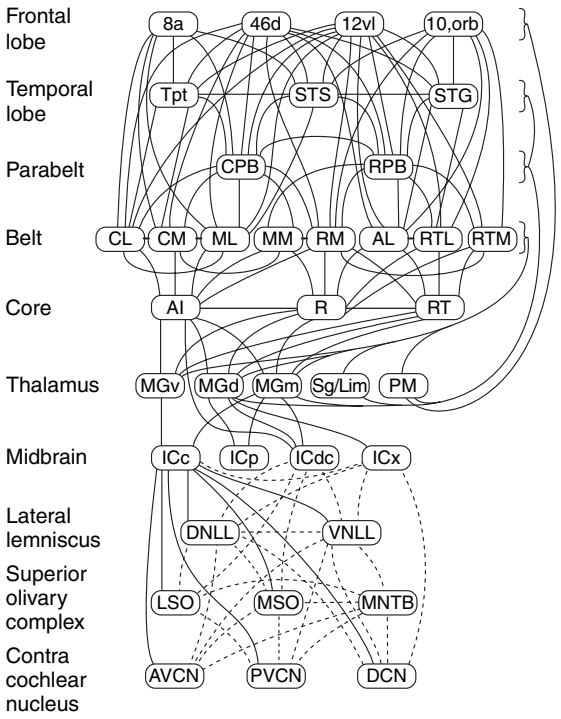

Figure 1 Subcortical and cortical connections of the auditory system in primates. Subdivisions are abbreviated within outlined ovals. Lines indicate connections between subdivisions. Dashed lines are based on studies in nonprimates that are presumed to exist in primates. Thalamic projections broadly distributed to cortical areas at a given level are indicated by brackets. Important connections of temporal lobe areas (temporoparietal (Tpt) and superior temporal sulcus (STS)) with posterior parietal areas are not included, but posterior parietal targets provide another route to the frontal cortex, especially to premotor areas. The cochlear nuclear complex includes anteroventral cochlear nuclei (AVCN), posteroventral cochlear nuclei (PVCN), and dorsal cochlear nuclei (DCN). The superior olivary complex includes the lateral superior olivary (LSO) and medial superior olivary (MSO) and nuclei, and the medial nucleus of the trapezoid body (MNTB). The lateral lemniscus includes the dorsal nucleus lateral lemniscus (DNLL) and ventral nuclear lateral lemniscus (VNLL). The inferior colliculus of the midbrain includes the inferior colliculus central nucleus (ICc), the inferior colliculus pericentral nucleus (ICp), the inferior colliculus dorsal cortex (ICdc), and the inferior colliculus external nucleus (ICx). The auditory thalamus includes the ventral medial geniculate (MGv), dorsal medial geniculate (MGd), medial (or magnocellular) geniculate (MGm) nuclei, as well as the suprageniculate (Sg) nucleus, the limitans (Lim) nucleus, and the medial pulvinar (PM) nucleus. In the cortex, the auditory core includes the primary auditory (A1) area, the rostral (R) area, and the rostrotemporal (RT) area. The auditory belt includes caudolateral (CL), caudomedial (CM), middle lateral (ML), medial middle (MM), rostromedial (RM), anterolateral (AL), rostrotemporal lateral (RTL), and rostrotemporal medial (RTM) areas. The parabelt is divided into caudal parabelt (CPB) and rostral parabelt (RPB) regions. Auditory regions of the temporal lobe include the Tpt, cortex of the STS, and cortex of the superior temporal gyrus (STG). Area 8a is periarcuate (in macaques) cortex in the region of the frontal eye field. Area 46d is prefrontal cortex for working memory in the region of the principal sulcus of macaques. Area 12vl is ventrolateral prefrontal cortex. Area 10,orb is orbitofrontal cortex and the frontal pole.

auditory processing. Auditory inputs may mix with somatosensory and visual inputs at even secondary stages of cortical processing. The organization of auditory cortex has been extensively studied in only a few species of mammals. In these species, an understanding of cortical organization has only gradually emerged, and is generally incomplete, with tentatively proposed features. Thus, it is accurate to describe current proposals as theories of cortical organization.

In this chapter we emphasize a theory of cortical organization for the auditory system of primates (Kaas, J. H. and Hackett, T. A., 2005). This theory is based on the results of over 30 years of study. Most of the information comes from studies of Old World macaque monkeys, and several species of New World monkeys, with some relevant results from prosimian galagos, and especially recently, important contributions from studies on humans. The cortical system outlined here appears to apply broadly to anthropoid primates (monkeys, apes, and humans), and at least partly to prosimian primates. The human auditory system obviously has cortical specializations

for language, and the cortical systems in the two hemispheres are not completely symmetrical. We will only briefly discuss these specializations. The evidence that cortical auditory systems are somewhat asymmetrical in apes suggests that the specializations have broader functions than language, but that the specializations increased with selection for language ability. For purposes of comparison, we will also discuss the organization of auditory cortex in rodents, carnivores, and bats, while recognizing that very little is known about the auditory cortex of the many other branches of mammalian evolution.

3.45.2 Auditory Cortex in Primates

Early concepts of the organization of auditory cortex in primates were influenced by the interpretations of early results in cats. Thus, a single primary area, A1, was defined, bordered by a second area, A2. This view was subsequently modified in that the concepts of an A2 and a single primary area were replaced by a proposed core of two or three primarylike areas, surrounded by a belt of secondary areas, and areas in several additional higher stages of cortical processing (Figure 1).

3.45.3 First Level of Cortical Processing: The Core Areas

Primary or primarylike areas of auditory cortex in mammals have several characteristic features. Most importantly, they receive dense, topographically organized projections from the principal or ventral nucleus of the medial geniculate (MGv) complex. This projection allows neurons in the primary auditory cortex to be narrowly tuned to tone frequencies so that best (threshold) or characteristic frequencies can be identified for cortical neurons, and that neurons with similar and different best frequencies are systematically arranged to form an orderly frequency map. Primary maps proceed from representing high best frequencies to low best frequencies across one dimension of the map, while best frequencies remain constant for contours across the other dimension of the map, the isofrequency contours. The terminal arbors of MGv axons in A1 and the intrinsic horizontal connections tend to be distributed along the isofrequency contours (see Ojima, H. and Takayanagi, M., 2004 for review). Primary auditory areas are also histologically specialized for having neurons with high levels of activity and constrained receptive fields. Thus, layer four of the primary auditory cortex is densely packed with small neurons, this area is usually more densely myelinated than surrounding areas, and they express high levels of the metabolic enzyme, cytochrome oxidase. In some mammals, including anthropoid primates, they also express high levels of the enzyme for deactivating the neuromodulator, acetylcholinesterase (AChE), and high levels of the calcium binding protein, parvalbumin (Hackett, T. A. *et al.*, 2001). Most or all primates appear to have three such primary areas, termed A1 (as the original primary area), R (for the area rostral to A1), and RT (for the rostrotemporal location).

The auditory core in macaque monkeys is located in the cortex of the lower bank of the lateral sulcus (Figure 2). Along the caudorostral (anteroposterior)

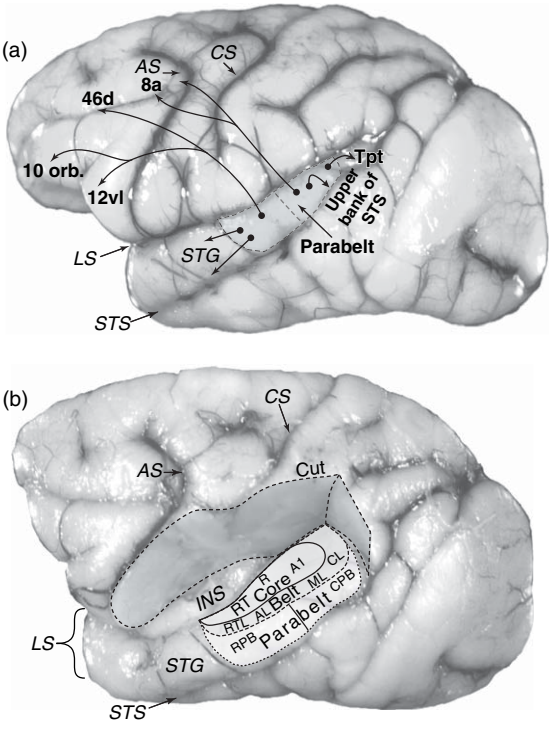

Figure 2 The locations of core, belt, and parabelt auditory fields on a lateral view of the brain of a macaque monkey. (a) An intact brain with the region of the parabelt outlined on the surface of the superior temporal gyrus (STG) located between the lateral sulcus (LS) and the superior temporal sulcus (STS). The frontal eye field is on the rostral bank of the arcuate sulcus (AS), while the central sulcus (CS) divides motor cortex from somatosensory cortex. Connections of the parabelt divisions are indicated with arrows. (b) In this view, the cortex overlying the lower bank of the LS and the insula (an island of cortex in another plane deep in the sulcus) has been exposed by cutting away (cut) the overlying portion of parietal and frontal cortex. See Figure 1 for abbreviations.

extent of the fissure, A1 is most caudal, followed by R and then RT.

The three areas form a band that is six or seven times longer than its width. Architectonically, the core is very distinct from surrounding cortex, while the three core areas are very similar. In brain sections cut parallel to the cortical surface, so that all boundaries of the core can be appreciated in a single section, sections processed for parvalbumin (Figure 3) and other markers clearly reveal the extent of the core. In general, the primarylike architectonic features are most pronounced in A1, and least pronounced in RT. A1 is the largest of the three core areas.

The position of the core varies somewhat relative to the lateral sulcus across primate species, so that in monkeys with a shallow sulcus, especially in the small marmoset monkeys, the core extends on to the surface of the temporal lobe (Aitkin, L. M. *et al.*, 1988; Luethke, L. E. *et al.*, 1989; Wang, X. M. M. *et al.*, 1995). As humans have a deep lateral fissure that contains additional fissures, the core is rotated in a manner that places A1 deepest in the fissure (Hackett, T. A. *et al.*, 2001).

The core was first divided into two areas, A1 and RL (for rostrolateral) by Merzenich M. M. and Brugge J. F. (1973), based on differences in tonotopic organization. Tones from high to low frequencies are represented in a caudomedial to rostrolateral sequence across A1, and in a reversed sequence across RL or R (Figure 4).

Later Imig T. J. *et al.* (1977) also used microelectrode recordings to identify these two fields in New World owl monkeys, while renaming RL the R area. Morel A. and Kaas J. H. (1992) subsequently defined the RT area as a third tonotopic representation, reversing the pattern in R to proceed from high to low in a caudorostral sequence. Recordings from RT have been limited, but good evidence for RT tonotopic organization has recently been obtained by Wang X. M. M. and co-workers (personal communication). In humans so far, functional magnetic resonance imaging (fMRI) data provide evidence of two tonotopic maps (Formisano, E. *et al.*, 2003) that appear to correspond to A1 and R of monkeys. As the shape of the auditory core is very similar in apes and humans to that of monkeys (Hackett, T. A. *et al.*, 2001), there is certainly room for three representations in the human core. In monkeys, MGv projects to A1, R, and RT (e.g., Morel, A. and Kaas, J. H., 1992; Morel, A. *et al.*, 1993; Hashikawa, T. *et al.*, 1995), providing further evidence of primary features for all three areas. As neurons in R remained responsive to tones after a lesion of A1 (Rauschecker, J. P. *et al.*, 1997), it is clear that A1 and R (and most likely RT) are independently activated by MGv projections.

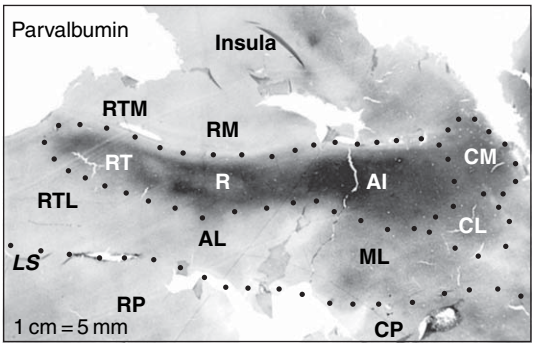

Figure 3 The core is histologically distinct from the surrounding belt and parabelt. Here the auditory region has been unfolded and flattened so that brain sections can be cut parallel to the surface. This allows all of the boundaries of the auditory cortex to be seen in a single brain section. A brain section has been processed for parvalbumin, a calcium-binding protein that is found in cortical areas of high neural activity. Although the brain section is somewhat damaged, the dark region expressing high levels of parvalbumin clearly defines the auditory core. Note that of the three core areas, RT expresses the lowest level of parvalbumin, and that belt areas CM and CL express moderate levels. The important point is that the core can be defined histologically, which both helps verify the concept of the core and aids identification in physiological studies. See Figure 1 for abbreviations. Adapted from Hackett, T. A., Stepniewska, I., and Kaas, J. H. 1998. Subdivisions of auditory cortex and ipsilateral cortical connections of the parabelt auditory cortex in macaque monkeys. J. Comp. Neurol. 394, 475–495. Wiley-Liss, with kind permission.

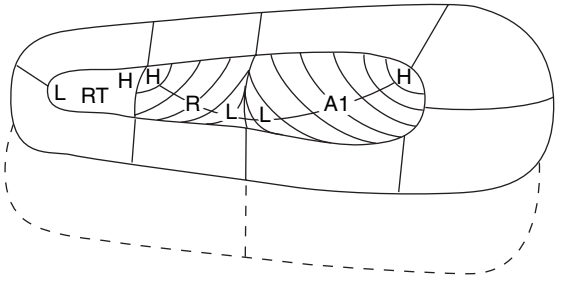

Figure 4 The tonotopic organization of A1, R, and RT of the core. A1 represents the frequencies of acoustic stimuli from high to low in a caudomedial to rostrolateral sequence across the area (compare with Figure 2). This pattern reverses in R and again in RT, providing the principle basis for dividing the core into three areas. The isofrequency contours in A1 and R are represented by curved lines. Along these contours, neurons respond best to the same frequency. RT has not been studied in enough detail to allow isofrequency contours to be depicted. See Figure 1 for abbreviations.

Neurons in the core areas project subcortically, to the adjoining auditory belt, and to matching locations

in the core of the other hemisphere (Luethke, L. E. *et al.*, 1989; Morel, A. and Kaas, J. H., 1992; Morel, A. *et al.*, 1993). Projections from each core area are most dense to adjoining portions of the belt, but sparse connections also exist between core areas and more distant belt areas. The three core areas also project to each other, most densely with the adjoining area or areas. Thus, the three core areas appear to function by modifying the signal sent by the thalamus, principally from the MGv nucleus, but also dorsal auditory thalamus (MGd) and medial (or magnocellular) auditory thalamus (MGm), and relaying the modified information in parallel to adjoining belt areas, to each other, to homologous belt areas in the other hemisphere, and via feedback connections to the MG complex and the inferior colliculus.

Quite surprisingly, there is evidence that a few neurons in the core, lateral belt and parabelt, as well as in the polysensory cortex of superior temporal sulcus (STS), project directly to portions of primary visual cortex subserving peripheral vision (Falchier, A. *et al.*, 2002; Rockland, K. S. and Ojima, J., 2003). The role of these unexpected auditory inputs to the earliest stage of visual processing is uncertain, but such presumably modulatory inputs could enhance the visual recognition, and help direct visual attention toward the source of a sound.

3.45.4 Second Level of Cortical Processing: The Areas of the Auditory Belt

The auditory belt consists of a narrow 2–3 mm fringe of cortex surrounding the core. The belt is defined as the surrounding zone with dense connections with the core. Remarkably, nearly all of the ipsilateral cortical connections of the core are with this narrow fringe of cortex: there are almost no connections with more distant cortical locations (however, see above). In this way, core auditory cortex differs from primary visual cortex (V1) in primates where V1 has dense connections with the middle temporal (MT) visual area, which is displaced from the V1 border into the upper temporal lobe, and differs from primary somatosensory cortex, area 3b, which has long connections with the second somatosensory (S2) area and the parietal ventral (PV) area in the upper bank of the lateral fissure. The belt cortex is easily distinguished from the core in that it is architectonically much less differentiated than the core, reflecting less specialization than the core for receiving relatively unprocessed sensory information and maintaining high levels of neural activity. Thus, layer four is less pronounced, the cytochrome oxidase levels of layer four are reduced, and less AChE and parvalbumin (Figure 3) are expressed. The belt receives only sparse inputs from MGv, but instead has most of its thalamic inputs coming from MGd and MGm. As neurons in the belt reflect a second level of cortical processing, these neurons are generally more depressed by anesthetics. They are also less responsive to pure tones, and more responsive to complex auditory stimuli. Nevertheless, many neurons are responsive enough to tones or frequency-centered narrow bands of noise so that best frequencies can be estimated, and frequency (tonotopic) patterns can be determined (Rauschecker, J. P. *et al.*, 1995). Such tonotopic patterns, together with patterns of cortical connections, population differences in neuron responses to auditory stimuli, and subtle differences in cortical architecture have been used to subdivide the core into as many as eight presumptive areas. For Brodmann K. (1909), a cortical area was a functionally distinct subdivision of the brain. As areas may have functionally different subunits (modules), an area should have an overall unifying feature, such as a single tonotopic map, as in A1, R, and RT. Some of the proposed subdivisions of the belt remain tentative areas because such unifying features have not been revealed yet.

Presently, there is evidence that three auditory belt areas have separate representations of cochlea. A best-frequency series for neurons across the caudorostral length of the mediolateral (ML) area parallels that of A1 and proceeds from high to low best frequencies. A reverse sequence from low to high in the anterior lateral (AL) area parallels the tonotopic organization of R. As the complete tonotopic representation in RT has only recently been determined, the possibility of frequency representations in the rostrotemporal lateral (RTL) and rostrotemporal medial (RTM) banding fields has not been explored. Likewise, little is known about the less accessible fields medial to R (RM) and medial to A1 (middle medial (MM)), but their respective association with R and A1 via dense interconnections suggests that tonotopic patterns exist. The two areas that form the caudal cap of A1 also appear to contain crude tonotopic representations in that neurons near the A1 border are more responsive to high frequencies than neurons more displaced from that border (Kajikawa, Y. *et al.*, 2005).

The cortical connections of the more accessible lateral belt areas, AL and ML, are most known (Figure 5).

ML is interconnected with all three core areas, but most densely with A1 and only sparsely with R. ML has connections with a number of belt areas, but most densely with adjoining areas AL and caudolateral (CL). Dense connections are with the adjoining caudal division of the auditory parabelt (CPB) and sparser connections are with the rostral parabelt (RPB). Other ipsilateral connections involve dorsal portions of prefrontal cortex. Callosal connections with the other hemisphere are focused in ML. AL has a similar pattern of cortical connections, with the difference that connections with R, rather than A1, are most dense and connections involve nearby belt areas, the RPB more than the CPB, a matching location in the other hemisphere and more ventral locations in the frontal lobe.

The more ventral targets in the parabelt and frontal lobe for AL and ML are part of the support for the theory that two main functional streams of interconnected areas emerge from the early levels of auditory processing in primates; a ventral stream more specialized for sound identification and a dorsal stream more specialized for localizing sound sources (what and where pathways; see Kaas, J. H. and Hackett, T. A., 1999; Romanski, L. M. *et al.*, 1999a; 1999b; Rauschecker, J. P. and Tian, B., 2000). Further evidence for these streams is discussed in subsequent sections of this chapter.

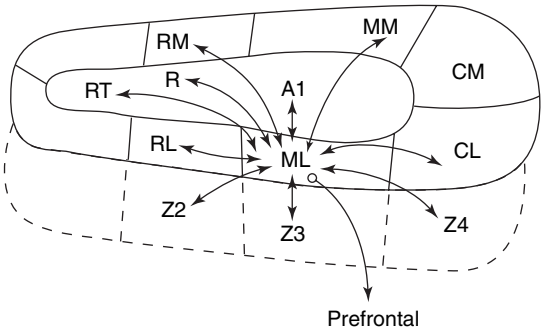

Figure 5 Cortical connections of areas of the auditory belt. Here the connections of the middle lateral (ML) area are indicated by arrows. The dashed arrows signify sparser connections. The connections of only a few of the belt areas have been determined, but they all are expected to have connections with nearby core and belt areas, as well as the parabelt. Z2–Z4 are arbitrary zones in the parabelt. Z1 (not indicated) and Z2 correspond to the rostral parabelt and Z3 and Z4 correspond to the caudal parabelt. See Figure 1 for abbreviations.

Two areas of the belt have been more extensively studied. The caudomedial (CM) area and to a lesser extent, the CL area, stand out as fields that express slightly more parvalbumin (Figure 3) and cytochrome oxidase than other belt areas, and thus appear to be somewhat corelike. Merzenich M. M. and Brugge J. F. (1973) first defined CM of macaque monkeys in roughly the position of CM as illustrated here (Figure 1). As many neurons in CM responded well to pure tones, Merzenich M. M. and Brugge J. F. determined best frequencies for neurons at enough sites in CM to suggest that the area represents high to low best frequencies in a progression away from the A1 border. This result has been confirmed by Kajikawa Y. *et al.* (2005) in an extensive comparison of neuron response properties in A1 and CM. In both areas, neurons responded well to broadband noise and to tones. As a population, neurons in CM had shorter response latencies, lower thresholds, and broader frequency tuning than neurons in A1. CM was tonotopically organized with neurons selective for middle frequencies under-represented. While the response characteristics and architectonic features of neurons suggest a close relationship to the core, CM is not included in the core because these features are muted compared to the core, and more important, CM depends greatly on inputs from A1 for activation. Rauschecker J. P. *et al.* (1997) found the responsiveness of neurons in CM to be greatly depressed by lesions to A1, providing evidence that CM is serially activated by A1. This is consistent with the anatomical evidence that MGv projects densely to A1 but only sparsely to CM (Hackett, T. A. *et al.*, 2007; Molinari, M. *et al.*, 1995; Rauschecker J. P. *et al.*, 1995; 1997). Nevertheless, some responsiveness remains in CM after A1 lesions. This responsiveness is likely mediated by MGd and MGm inputs to CM, as the responsive neurons do not have A1 qualities. The overall shorter latencies of CM neurons to sounds may be mediated by MGm inputs that involve larger diameter axons.

The most remarkable feature of CM is that it has many neurons that respond to somatosensory stimuli, especially light touch on the head and neck (Schroeder, C. E. *et al.*, 2001; Fu, K. M. *et al.*, 2003). Many neurons respond to both somatosensory and auditory stimuli. The source of this somatosensory input is presently uncertain, although CM does have connections with regions of cortex in the lateral sulcus that are likely to be somatosensory, and locations in the ventral thalamus that also could be somatosensory (de la Mothe, L. *et al.*, 2006a; 2006b; Smiley, J. F. *et al.*,

2007; Hackett, T. A., *et al.*, 2007). What is remarkable about this finding is that a second-level auditory area is highly responsive to somatosensory stimuli, and the area is clearly multisensory (or bisensory). Second-level visual or somatosensory areas are not multisensory. The significance of this early combination of somatosensory and auditory stimuli is as yet uncertain, but the ipsilateral cortical connections of CM are largely to the CPB, and the adjoining temporoparietal (Tpt) region (see below). These are considered components of the dorsal stream of auditory processing. Thus, CM may be more involved in contributing to spatial-processing stimuli, and may combine sounds and touch to focus attention toward parts of the body.

In humans, fMRI studies show that a region adjoining the auditory core is activated by both somatosensory and auditory stimuli (Foxe, J. J. *et al.*, 2002). These results support anatomical evidence that an area corresponding to CM exists in humans (Hackett, T. A. *et al.*, 2001).

3.45.4.1 Caudolateral Area

Located just lateral to CM, the CL area is a field that can be identified architectonically as it expresses less parvalbumin than adjoining areas CL and A1, but more than adjoining ML and Tpt (Figure 3). CL is also tonotopically organized as neurons near the A1 border respond better to band-passed noise bursts centered at high frequencies, while those near the caudal border prefer low frequencies (Rauschecker, J. P. *et al.*, 1995). Thus, CL and CM have parallel tonotopic organizations. Thalamic inputs are from MGd and MGm, rather than MGv (Molinari, M. *et al.*, 1995), and cortical connections are with A1, adjoining areas of the belt, the CPB, and adjoining Tpt. Neurons sensitive to the spatial locations of sounds are reported to be more common in CL than other parts of the lateral belt (Tian, B. *et al.*, 2001), but they are also found in CM (Recanzone, G. H. *et al.*, 2000b). Providing information about the locations of sound sources is a basic function of the dorsal stream of auditory cortical areas, and CL and CM have neuronal properties and cortical connections that are highly consistent with this function (Woods, T. M. *et al.*, 2006).

3.45.4.2 Middle Lateral and Anterior Lateral Areas

The portion of the lateral belt just lateral to A1 is known as the middle lateral area, ML (Rauschecker, J. P. *et al.*, 1995). The region had been previously called the lateral field, L, by Merzenich M. M. and Brugge J. F. (1973), and the posterior lateral field, PL, by Fitzpatrick K. A. and Imig T. J. (1980). ML contains a coarsely tonotopic representation of high-to-low frequencies from caudal to rostral in parallel with the representation in A1 (Merzenich, M. M. and Brugge, J. F., 1973; Morel, A. *et al.*, 1993; Rauschecker, J. P. *et al.*, 1995; Kosaki, H. *et al.*, 1997). ML has dense connections with A1, and sparse connections with R that are weakly topographical (Fitzpatrick, K. A. and Imig, T. J., 1980; Aitkin, L. M. *et al.*, 1988; Luethke, L. E. *et al.*, 1989; Morel, A. *et al.*, 1993). As for other belt areas, thalamic inputs are from MGd and MGm, rather than MGv (Morel, A. and Kaas, J. H., 1992). Other connections are with CL, MM, and AL of the belt. ML is strongly connected with the CPB. ML also has connections with cortex just rostral to the frontal eye field (Morel, A. and Kaas, J. H., 1992; Romanski, L. M. *et al.*, 1999a; 1999b). These connections may indirectly provide auditory information that directs eye movements via the frontal eye field to sound sources of interest. Thus, the frontal cortex connections, as well as those to the CPB, associate ML with the dorsal stream of processing. However, neurons in ML reportedly respond better to recorded monkey calls than energy-matched complex sounds (Rauschecker, J. P. *et al.*, 1995), and sound recognition would be a postulated feature of the ventral stream.

The AL area occupies the portion of the lateral belt that borders area R (Imig, T. J. *et al.*, 1977). Neurons in AL are broadly tuned to tone frequency, but they form a tonotopic sequence from caudal neurons preferring low frequencies to rostral neurons preferring high frequencies in parallel with the tonotopic organization of R (Imig, T. J. *et al.*, 1977; Morel, A. *et al.*, 1993; Rauschecker, J. P. *et al.*, 1995; Kosaki, H. *et al.*, 1997). Thalamic inputs are from MGm and MGd, as well as the medial pulvinar and posterior thalamus (Morel, A. and Kaas, J. H., 1992; Molinari, M. *et al.*, 1995). AL has dense connections with R, less dense connections with A1, connections with other belt areas, and more dense connections with the RPB than the CPB (Fitzpatrick, K. A. and Imig, T. J., 1980; Morel, A. and Kaas, J. H., 1992; Hackett, T. A. *et al.*, 1998). AL connections that are more distant are with lateral prefrontal cortex and orbital frontal multisensory cortex (Romanski, L. M. *et al.*, 1999a; 1999b), consistent with a proposed role in the ventral-processing stream devoted to sound recognition and evaluation. In support of this proposed role of AL, Tian B. *et al.* (2001) reported that

neurons in AL were more tuned to monkey vocalizations and less to sound source localization than neurons in CL.

3.45.4.3 Middle Medial and Rostromedial Areas

The areas of the medial belt have not been extensively explored, largely because of their less accessible position deep in the lateral sulcus. However, the MM area and the RM field receive dense projections from their respective adjoining core areas, A1 and R (Imig, T. J. *et al.*, 1977; Morel, A. and Kaas, J. H., 1992; Morel, A. *et al.*, 1993; de la Mothe, L. A. *et al.*, 2006a). This raises the possibility of crude tonotopic organization in both areas. Other connections are with belt areas CL and MM (Morel, A. *et al.*, 1993) and with the parabelt, with MM more connected with the CPB and RM more with the RPB (Hackett, T. A. *et al.*, 1998). Injections of tracers to frontal granular cortex labeled neurons in the location of MM (Romanski, L. M. *et al.*, 1999a; 1999b). Little is known about the response properties of neurons in MM and RM other than their poor response to tones (Merzenich, M. M. and Brugge, J. F., 1973). RM is expected to be more involved in ventral-stream processing and MM in dorsal-stream processing.

3.45.4.4 RTM and RTL Areas

While the evidence for a third core area, RT, is fairly solid, little is known about the proposed bordering belt areas, RTM area, and the RTL area. An injection in RT demonstrated connections with both belt areas (Morel, A. and Kaas, J. H., 1992), and both areas have connections with the auditory parabelt (Hackett, T. A. *et al.*, 1998). Unfortunately, the location of the medial belt areas in the depths of the lateral sulcus has made it difficult to determine their connections fully. As noted above, area CM has neurons that respond to touch, and some of the cortical and thalamic connections may involve somatosensory structures. Cortex adjoining the medial belt in the depths of the lateral sulcus, on the insula, and on the upper bank of the lateral sulcus is largely or completely somatosensory in function, and short interconnections could mediate bisensory (somatosensory plus auditory) functions. At least two of the proposed somatosensory areas of the lateral sulcus, the PV area and the ventral somatosensory area (see Qi, H. X. *et al.*, 2002) have neurons that respond to auditory stimuli. Area PV, at least, appears to have connections with the medial belt (Disbrow, E. *et al.*, 2003). A study of neural metabolic activity in response to auditory stimuli implicates much of somatosensory cortex of the lateral sulcus in auditory functions (Poremba, A. *et al.*, 2003).

3.45.5 Third Level of Cortical Processing: The Auditory Parabelt Areas

In monkeys, the auditory parabelt occupies much of the sector of the superior temporal gyrus (STG) that adjoins the lateral belt (Figure 1). As the lateral belt is not markedly distinct in architectonic features from most of the adjoining cortex, and there is no evidence of one or more systematic representations of any parameter of sound, such as frequency, the auditory belt is defined by a unique feature of its cortical connection pattern. Injections of tracers in any part of the parabelt label large numbers of neurons in the auditory belt, but not the core (Hackett, T. A. *et al.*, 1998). Although injections in the belt may label a few neurons in the core, a series of injections across the length of the parabelt will fill the medial and lateral belt areas with labeled neurons while labeling only the occasional neuron in the core. The dense population of labeled neurons defines the belt well while outlining the core. The obvious interpretation of this pattern of connections is that all belt areas provide the major inputs to the parabelt, but the parabelt is virtually free of a direct influence from the core. Thus, the first, second, and third levels of processing in auditory cortex of primates are clearly defined. In contrast, the more widely distributed connections of early stages of processing the visual and somatosensory systems of primates complicates the assignment of cortical areas to levels (Felleman, D. J. and Van Essen, D. C., 1991).

The size of the parabelt suggests that it may contain several functionally distinct areas, but presently there is no clear evidence of how or if the region is subdivided. Hackett T. A. *et al.* (1998) divided the parabelt into RPB and CPB regions based on differences in connections. Most notably, the RPB has its most dense connections with the rostral belt, and the CPB has its most dense connections with the caudal belt. However, the belt connection pattern shifts from rostral to caudal as the locations of injections of tracers move from caudal to rostral in the parabelt. Thus, there appears to be no sharp border between

the RPB and the CPB where the connection pattern sharply changes. Based on these connections, the parabelt may be considered a single area, two areas, or possibly three or four. For convenience, we divide the region into rostral and caudal halves. Cortex is considered to be outside the parabelt when injections of tracers fail to label more than an occasional neuron in the belt.

The outputs of the parabelt are with several cortical targets. These diverse regions constitute the fourth level of processing where various systems interact, and a strict hierarchy of fields is no longer apparent. These targets of the parabelt are discussed in a subsequent section of this chapter.

Just as the lateral parabelt is defined by connections of the belt, it seems possible that cortex in the lateral sulcus could receive inputs from the belt and thus constitute an unrecognized medial parabelt. However, this is unlikely for several reasons. Most notably, the lateral parabelt has connections with both medial and lateral belt areas. Injections in the lateral belt areas do not label regions of cortex outside the medial belt in the lateral fissure. In addition, the cortex adjoining the medial belt is dominated, largely or completely, by somatosensory inputs. Nevertheless, it does seem likely (see above) that some connections between medial belt areas and somatosensory cortex of the lateral fissure do exist, but functionally this cortex would be much different from an auditory parabelt.

3.45.6 Levels of Auditory Processing Defined by Inputs from the Parabelt: Areas of the Fourth Level

All regions of cortex with direct connections with the parabelt can be considered a diverse, distributed, fourth cortical level of auditory processing. One of these regions in macaque monkeys is the cortex of the upper bank of the STS (Seltzer, B. and Pandya, D. N., 1994; Hackett, T. A. *et al.*, 1998). Much of this STS cortex is visual as well as auditory (see Cusick, C. G., 1997 for review; Poremba, A. *et al.*, 2003), and some of this cortex may be involved in localizing visual objects that emit a sound and recognizing that a given object is producing the sound (Recanzone, G. H., 2004). This cortex may be important in the ventriloquist effect where a nearby sound is attributed to an object that appears to be the sound source. The STS cortex appears to provide feedback connections to the lateral belt and parabelt indirectly to the core where visual facial and vocal expressions of monkeys interact to enhance or suppress neural activity (Ghazanfar, A. A. *et al.*, 2005).

The parabelt also distributes connections to adjoining parts of the STGr, including more rostroventral parts that appear to be largely auditory in function, and part of the proposed ventral auditory stream related to sound identification and evaluation. The STGr region has connections with orbital parts of the frontal lobe, where multisensory neurons, including some responsive to auditory stimuli, are found. This cortex is involved in evaluating the hedonistic or rewarding value of stimuli (Rolls, E. T., 2004). Thus, primary reinforcing attributes of complex stimuli are associated with otherwise neutral aspects. The dorsocaudal tip of the gyrus, a region referred to as Tpt (or STGc), also receives parabelt inputs. Neurons in Tpt respond to auditory, visual, and somatosensory stimuli (Leinonen *et al.*, 1980). As this cortex projects to the region of the frontal eye field in the frontal lobe, a role in directing attention and eye movements toward sound sources of interest is likely (Huerta, M. F. *et al.*, 1987). This portion of the temporal lobe may also be involved in providing auditory signals to adjoining posterior parietal cortex (see Lewis, J. W. and Van Essen, D. C., 2000). Regions of posterior parietal cortex, especially those in the intraparietal sulcus of macaque monkeys are known for receiving somatosensory and visual inputs to guide reaching, eye, and other movements via connections with motor and premotor areas of the frontal lobe (see Fang, P. C. *et al.*, 2005 for review). Neurons in one of these areas, the lateral intraparietal (LIP) area respond to auditory signals after training on sound localization tasks (Grunewald, A. *et al.*, 1999). LIP is an area involved in directing eye movements toward targets. While visual signals usually guide this behavior, responses to auditory signals can be acquired.

The CPB and, to a lesser extent, the caudal belt areas are interconnected with the frontal granular cortex in the region of the principal sulcus of macaque monkeys (Hackett, T. A. *et al.*, 1999; Romanski, L. M. *et al.*, 1999a; 1999b). This region of cortex that has been implicated in short-term or working memory (e.g., Funahashi *et al.*, 1989; Constantinidis, C. *et al.*, 2001). These auditory inputs could be used to guide a reach or eye movement after a short delay.

Finally, the RPB and areas of the rostral belt contribute to the cortex of the inferior frontal lobe including the orbital and polar regions (Hackett, T. A. *et al.*, 1999; Romanski, L. M. *et al.*, 1999a; 1999b). These

areas are thought to be involved in object identification and object evaluation (Rolls, E. T., 2004). Thus, information about sounds could contribute to the multisensory identification of objects and their evaluation as tasty, rewarding, or unpleasant.

While these auditory areas of the fourth level greatly expand the proportion of cortex involved in auditory processing, additional regions of cortex show increased metabolic activity in response to auditory stimuli (Poremba, A. *et al.*, 2003), and thus are involved in audition. However, most of these regions, as well as much of auditory cortex of the fourth level, are bisensory or multisensory, and are likely not to be mainly auditory in function. As bisensory convergence occurs in the auditory cortex as early as the second level in CM, multisensory integration appears to be especially emphasized at the cortical level in the auditory system (see Schroeder, C. E. *et al.*, 2003; Ghazanfar, A. A. *et al.*, 2005).

3.45.7 Auditory Cortex in Humans

The early stages of cortical auditory processing in humans appear to be similar to those of monkeys. Thus, there is an elongated core region (Hackett, T. A. *et al.*, 2001) that appears to contain A1 and at least one other tonotopically organized area (Formisano, E. *et al.*, 2003; Talavage, T. M. *et al.*, 2004), and belt and parabelt regions have been postulated (see Hackett, T. A., 2002; Talavage, T. M. *et al.*, 2004; Sweet, R. A. *et al.*, 2005; Hackett, T. A., 2007 for review). The cortex of the lateral sulcus of humans is more complexly folded than in monkeys, creating Heschl's gyrus where the auditory core has been rotated so that A1 is deeper in the lateral fissure than presumptive R and RT. In the auditory belt of humans, a region that is activated by both touch and sounds has been identified as a probable homolog of the belt area CM of monkeys (Hackett, T. A. *et al.*, 2001; Foxe *et al.*, 2002). In monkeys, core, belt, and parabelt areas may represent, in part, preprocessing stages for the recognition of communication sounds (Rauschecker, J. P., 1998), and these three levels of processing may function in a similar role for the preprocessing of language in humans (Lewis, J. W. *et al.*, 2005). As part of the specialization of the left cerebral hemisphere for language in humans, the left Heschl's gyrus is more caudal than the right (Penhune, V. B. *et al.*, 1996). Asymmetries between the left and right hemispheres, such as in the extent and course of the lateral sulcus, have been repeatedly used as anatomical evidence for the specialization of the left cerebral hemisphere for language in humans. Interestingly, such asymmetries have been described from the skull endocasts, reflecting brain sulci, of fossil hominids, and even in macaque monkeys, arguing that hemispheric specialization in auditory function have a long history, and were not initiated by the emergence of language. In general, as brains get bigger, the cost of the long connections between hemispheres increases, and concentrating functions in one hemisphere or the other reduces the need for such long connections. In humans, a region adjoining Heschl's gyrus is enlarged in the left hemisphere (the planum temporale) and this region appears to be important in language as part of Wernicke's area. In the frontal lobe, a premotor region is larger in the left hemisphere, constituting a central part of Broca's speech area (Foundas, A. L. *et al.*, 1996). This premotor region may have emerged as a specialization of the rostral part of ventral premotor cortex of other primates (Preuss, T. M., 1995; Petrides, M. *et al.*, 2005). The region thought to be homologous to Broca's area in great apes is larger in the left than the right hemisphere (Cantalupo, C. and Hopkins, W. D., 2001). As in monkeys, what and where processing streams have been proposed for humans (e.g., Clarke, S. *et al.*, 2005). However, current understandings of the numbers and types of areas involved in auditory processing in humans are limited, and the full extent of differences in human and monkey auditory systems is not known.

3.45.8 Auditory Cortex in Other Mammals

Although an auditory core and belt seem to characterize auditory cortex in all studied mammals, auditory cortex has not been studied in detail in most mammals. However, more is known about the auditory cortex in cats, rodents, and echolocating bats. The basic features of auditory cortex organization of these mammals are outlined here for comparison with those of primates. In brief, the evidence suggests that a core of two or three areas and a belt of a number of additional areas exist in carnivores, rodents, and bats. Areas known as A1, anterior auditory field (AAF), and posterior auditory field (P; see below) may be homologous parts of the core in these mammals. As of now, homologies across mammals in belt fields, if any, remain uncertain.

3.45.8.1 Cats and Other Carnivores

Until recently, domestic cats have been the preferred research animals for investigating the cortical organization of the auditory system. As a result, much is known about auditory cortex in cats. In brief, cats have three primarylike auditory areas, named in a rostrocaudal sequence (Figure 6), the AAF, primary auditory cortex (A1), and P.

All three areas contain systematic representations of sound frequencies (see Imig, T. J. and Reale, R. A., 1980). A1 was the first of the three to be recognized (Woolsey, C. N. and Walzl, E. M., 1942), and the term A1 reflects that distinction. A1 has bands of isofrequency representation that course dorsoventrally across the area, while high-to-low frequencies are represented from rostral to caudal. A second auditory area, A2, was also proposed as the result of these early landmark studies (Woolsey, C. N. and Walzl, E. M., 1942; Woolsey, C. N., 1960). The original A2 was thought to have a reversed tonotopic organization from that of A1, but this was a misinterpretation, apparently as the result of recordings from rostral low-frequency zones in AAF and caudal high-frequency zones in P. Currently, A2 is viewed as a typical belt area with neurons more broadly tuned to frequency, and a tonotopic organization in parallel to that in A1 (high to low in a rostrocaudal direction), much as belt areas parallel the tonotopic organizations of A1 and R in monkeys (Schreiner, C. E. and Cynader, M. S., 1984). AAF has tonotopic organization from high-to-low frequencies in a caudorostral direction, to mirror A1 in organization (Knight, P. L., 1977). P extends ventrally from the caudal pole of A1 in a tonotopic pattern that reverses from that in A1 so that low tones are represented dorsally next to A1 while progressively higher tones are represented in progressively more ventral locations. All three areas have the histological features of core sensory cortex, such as a well-developed layer four with a high expression of cytochrome oxidase. A ventroposterior (VP) area reverses the tonotopic organization of P, and VP may also be part of the auditory core. Areas AAF, A1, and P all receive inputs from the MGv suggesting that they all have primarylike functions as targets of parallel projections from the auditory thalamus (Imig, T. J. and Morel, A., 1983; Lee, C. C. *et al.*, 2004). Matched tonotopic regions in the three areas are interconnected (Imig, T. J. and Reale, R. A., 1980). The core area also projects to adjoining ventral, temporal, dorsoposterior (DP), and second (A2) belt areas, and to portions of cingulate and multimodal cortex (Imig, T. J. and Reale, R. A., 1980; Lee, C. C. *et al.*, 2004). Belt cortex dorsal to A1 and AAF in the suprasylvian sulcus, called the suprasylvian fringe, also has A1 and AAF connections.

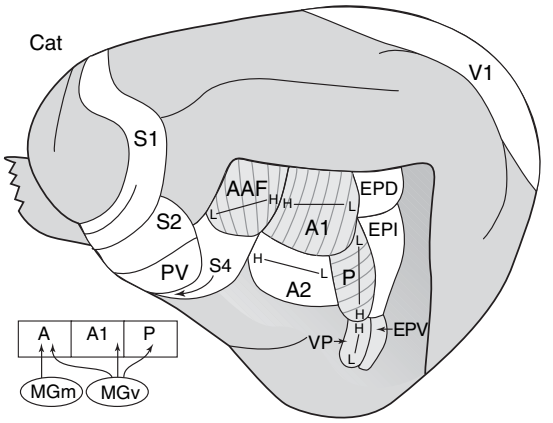

Figure 6 Proposed auditory areas in the domestic cat. Three primarylike areas include the anterior auditory field (A or AAF), the classical primary (A1) area, and the posterior (P) area. Each gets inputs from the ventral nucleus of the medial geniculate complex (MGv), although other inputs such as those from the medial (or magnocellular) geniculate nucleus (MGm), are more prevalent in A and P (see box diagram on lower left). AAF, A1, and P all have tonotopic organizations that reverse from each other at common borders. Parallel lines in these areas denote lines of isorepresentation. A2 and the ventroposterior (VP) area have crude patterns of tonotopic organization. Other auditory areas or regions include the suprasylvian fringe of auditory belt dorsal to A1 in the suprasylvian sulcus (not shown), and dorsal ectosylvian gyrus (EPD), intermediate ectosylvian gyrus (EPI), and ventral ectosylvian gyrus (EPV) sectors. The locations of somatosensory areas (primary somatosensory cortex, S1; second somatosensory area, S2; fourth somatosensory area, S4 – see arrow; parietal ventral (PV) area) and primary visual cortex (V1) are shown for reference.

Overall, cats have an auditory system that is characterized by the number of auditory areas that interconnect to form several parallel processing streams. Auditory inputs join somatosensory and visual inputs in multisensory cortex that provides an important projection to the superior colliculus to help direct eye and head movements toward stimuli of interest (Stein, B. E. *et al.*, 2004). At least superficially, the complex array of auditory areas in cats resembles that of primates, but homologies between areas are uncertain. Most notably, A1 of cats appears to have the opposite order of tonotopic representation of A1 of monkeys, where posterior A1 represents high, not low, tones. Thus, A1 of cats resembles area R of monkeys in tonotopic organization. This may be no more than a difference in rotation of the auditory

core as cortex expanded in the evolution of primates and carnivores. Uncertainties in the homologies of even A1 suggest the difficulty of postulating further homologies in cortical auditory areas in the primate and carnivore taxa. Other carnivores appear to resemble cats in the organization of auditory cortex, although relevant information is limited. Dogs have an AFF and A1 with reversed tonotopic organization as in cats, but clear evidence for a third representation in P is lacking (see Malinowska, M. and Kosmal, A., 2003). There is evidence for other fields, but they have not been well defined. Ferrets have an A1 with a tonotopic organization as in cats while two fields mirror A1 in tonotopic organization ventral to the low-frequency portion of A1 (Bizley, J. K. *et al.*, 2005). AAF of ferrets proceeds from high to low tones along the rostral border of A1 more in parallel with the progression in A1 than a reversal. Studies on these and other carnivores could usefully help identify the basic features of auditory cortex organization in carnivores.

3.45.8.2 Rodents

Rodents also have a corelike area with a surrounding belt of secondary auditory cortex. Because rodents are very convenient laboratory animals, auditory cortex has been studied in a number of rodents, including rats, mice, gerbils, guinea-pigs, squirrels, and chinchillas. However, a number of different schemes for how auditory cortex is organized have been generated, along with clear inconsistencies across schemes. Most notably, A1 has been described as having a rostrocaudal tonotopic organization from high to low tones in some rodents, and from low to high tones in other rodents. Other adjoining areas are variously named and described in rodents. One proposal with considerable experimental support is that of Scheich H. and Zuschratter W. (1995) for gerbils (Figure 7).

According to this proposal, gerbils have three areas, AAF, A1, and DP that are arranged and have tonotopic progressions much like AAF, A1, and P in cats. All three areas may be considered core areas in that they receive parallel inputs from the MGv nucleus (Budinger, E. *et al.*, 2000b), although the inclusion of DP in the core is somewhat questionable. At least ventrally, a belt of secondary areas has been defined. The interconnections of these auditory areas have been described by Budinger E. *et al.* (2000a). In other rodents, especially guinea-pigs, a dorsal belt of secondary areas has been identified (Wallace, M. N. *et al.*, 2000; Horikawa, J. *et al.*, 2001), so it is reasonable

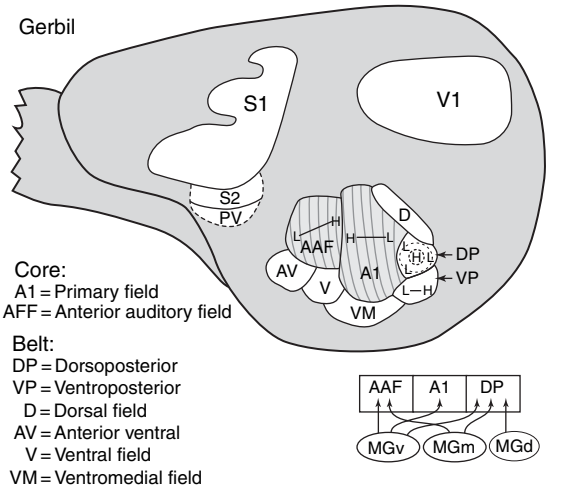

Figure 7 Proposed auditory areas in one of the more studied rodents (gerbil). In this and several other studied rodents, three primarylike areas have been identified, including a primary (A1) area with a representation of high-to-low frequencies in a rostrocaudal direction, much as in cats (Figure 6). The anterior auditory field (AAF) reverses this organization, closely resembling AAF of cats. Lines of isorepresentation are indicated in A1 and AFF. The posterior (P) area of other rodents has been divided here into dorsal (DP) and ventral (VP) components, with a more complex tonotopic organization in DP than VP. All three areas (AAF, A1, and P or DP) receive inputs from the ventral division of the medial geniculate complex (MGv), with the magnocellular division (MGm) projecting more to AAF and DP than A1, and the dorsal division (MGd) projecting more to DP (box diagram on lower right). Core and belt areas are defined in the figure. The locations of somatosensory areas S1, S2, and parietal ventral (PV) area and primary visual cortex (V1) are shown for reference. Auditory areas are based on Scheich H. and Zuschratter W. (1995).

to postulate both ventral and dorsal belts in rodents. The three corelike areas have also been identified in rats as areas A, A1, and P (Doron, N. N. *et al.*, 2002) or AV, A1, and PD (Horikawa, J. *et al.*, 1988) with each field being a mirror image of the adjoining field in tonotopic organization. Mice have at least the AAF and A1 core fields, as do chinchillas. Squirrels and guinea-pigs have at least two core fields, but their tonotopic organizations suggest that the area identified as A1 is not the same as A1 in other rodents.

3.45.8.3 Bats

The organization of auditory cortex in echolocating bats has been investigated because of great interest in the neural mechanisms of echolocation. In the

mustached bat (*Pteronotus parnellii*), Suga N. (1990) described a large A1 proceeding from representing high-to-low tones in a rostrocaudal sequence, as in A1 of cats, with a major overrepresentation of the high echolocating frequency range. In the echolocating horseshoe bat (*Rhinolophus rouxi*), Radtke-Schuller S. and Schuller G. (1995) have described an A1 again representing high-to-low frequencies in a rostrocaudal direction, and adjoining AAF and P DP fields with reversed tonotopic orders. Thus, A1 has an auditory fovea such that the relevant echolocating frequencies occupy a large part of A1. These bats also have a number of adjoining auditory areas that appear to be specialized for echolocating functions, but their relationship to auditory areas in other mammals is uncertain. In the big brown bat (*Eptesicus fuscus*; Dear, S. P. *et al*., 1993) and Seba's short-tailed bat (*Carollia perspicillata*; Esser, K. H. and Eiermann, A., 1999) a tonotopically organized area, AAF, has been described just rostral to A1 with a mirror image organization of A1. Again, there was evidence for several specialized auditory fields adjoining A1 and AAF. Connections of A1 and DP with the ventral subdivisions of the MGv suggest that at least these two areas can be considered core areas (Radtke-Schuller, S., 2004). Little is known about the cortical connections of auditory fields in bats, but a core of at least two areas and a surrounding belt would seem to characterize bats as well as primates, rodents, and carnivores.

3.45.9 Conclusions

While it would be useful to have data on a greater range of mammals, it seems likely that most mammals have a core of two or three primary areas that process auditory information in parallel from the MGv complex. These two or three core areas were likely retained from early mammal ancestors. Similarities between core areas within and across mammal groups, and differences in the tonotopy of areas given the same name (e.g., A1), suggest that mistakes in identification have been made. Such misidentifications, to the extent that they have occurred, may reflect real differences in homologous fields across taxa. Quite possibly, core areas have been differentiated and specialized in various ways in the major lines of mammalian evolution, so that homologous core areas appear different. In all mammals, the core areas distribute to adjoining secondary fields, and these fields spread auditory information even further. In monkeys and humans, there is evidence that rostral and caudal core, belt, and parabelt regions differentially distribute auditory information into a ventral stream for sound identification, and a dorsal stream for sound localization. This view is obviously an oversimplification, but different, partially overlapping arrays of areas specialized for specific types of functions are targeted by the two streams. Each stream further divides as an expanding number of cortical areas become involved in auditory processing. The functions of most of these higher order areas are not solely auditory, as multisensory processing emerges as early as in the auditory belt. While an oversimplification, the dual-stream hypothesis, which has well-established counterparts in visual and somatosensory cortex, remains a concept that is useful in directing further research. The complete connection pattern and the physiological properties of neurons of the belt areas are not yet well understood in any mammal, but considerable progress has been made in characterizing area CM of the auditory belt in monkeys. In addition, the results of a number of studies have started to inform us about the lateral belt. The medial belt is less accessible and harder to investigate, but studies of connections are ongoing, and much more will be known in the future. The concept that the parabelt has at least two divisions has usefully lead to further research, but a better understanding of the functional properties of neurons is needed, as well as evidence on how or if the parabelt is subdivided into functionally distinct parts. The broad outlines of the distribution of auditory information to higher levels and thereafter is now broadly understood, but there is much yet to learn. The sparse connections of belt and parabelt auditory areas with visual areas including V1, has only recently become apparent. The functional significance of such sparse connections is uncertain, and perhaps difficult to investigate.

Cats have an auditory system that includes a number of fields and a complex array of cortical connections. This must represent the independent evolution of a complex cortical processing system from that in primates, although a core and belt organization were probably retained from a common ancestor in lines leading to both primates and carnivores. A better understanding of the similarities and differences in auditory processing at the cortical level could be informative and interesting. Much more could be done with rats and other rodents, given the progress in outlining cortical areas in rats and other rodents. Of course, there is much to learn about

auditory cortex in understudied and unstudied mammals, and there may be surprising specializations in some of these mammals, as there are in bats. As for bats, more understanding of auditory cortex connections is needed. It remains unfortunate that auditory cortex organization in nonecholocating fruit bats has not been studied, as their less specialized cortical system could highlight the changes needed for echolocation.

Glossary

artificial neural network A computer algorithm that has been applied to the study of cortical representation of sound-source locations. The network first is trained with examples of cortical responses to particular sound sources, and then the trained network is used to estimate the source location producing other cortical responses.

azimuth The horizontal dimension of space. In the context of this review, azimuth is the location of a sound source relative to the frontal midline measured as the angle about the vertical axis.

maximum likelihood estimator A statistical procedure that can be used to determine which of a set of stimuli is most likely to have produced a particular neural response.

precedence effect Refers to a group of phenomena in which two spatially discrete sound sources are perceived as a single source. Depending on the relative timing of the two sounds, the fused source is reported as intermediate in location between the two sources or at the location of the leading sound.

spatial receptive field The region of auditory space within which presentation of a sound elicits a criterion response from a cortical neuron.

tonotopic organization: A neural representation of the audible frequency range in which individual neu-

rons are sharply tuned for frequency and the tuning of neurons varies systematically as a function of location within a brain nucleus or cortical area.
virtual auditory space: A simulation of a spatially localized sound source produced by sounds presented through headphones. A virtual target is synthesized by filtering an arbitrary sound source with the directional filter properties of the head and external ears that have been measured previously for an actual sound source.

3.46.1 Introduction

One can say with some confidence that an intact auditory cortex is essential for normal sound localization. That assertion is based on studies of behavioral consequences of lesions and on studies of functional inactivation (reviewed in Section 3.46.4). Beyond that, however, the specific role of auditory cortex in sound localization, and more generally in spatial hearing, is not so clear. We know that acoustic cues for sound localization are encoded in patterns of activity in the two auditory nerves, we can point to specific brainstem nuclei that extract particular binaural and spectral shape cues for sound-source location, and we infer that those cues are integrated in the ascending auditory pathway to at least begin to form the neural correlates of auditory objects. Nevertheless, one cannot say with certainty how much of that integration is accomplished by the brainstem and how much remains to be done at the cortical level. Neither is it clear to what extent spatial processing might take place in a hierarchical manner among various cortical fields nor, indeed, is it clear whether any particular cortical area or areas have a special role in spatial hearing.

Although many questions remain, substantial progress has been made on these issues in the past 5–10 years, due in part to developments in virtual auditory space technology, computational algorithms for recognition of patterns of cortical activity, methods for functional inactivation of specific cortical areas, and functional imaging of the human brain. This chapter begins by reviewing the spatial sensitivity of auditory cortical neurons, including responses to stimuli that vary dynamically in space and time. We then explore how it is that the location of a sound source is written down in patterns of cortical activity and how one might read those patterns. Next, we review the behavioral consequences of destruction or inactivation of particular auditory cortical areas. We review briefly the rapidly growing body of results from studies of the human brain using functional imaging techniques. Finally, we draw some broad conclusions and list some key areas for future research.

3.46.2 Spatial Sensitivity of Cortical Neurons

The cat and, to a lesser degree, the ferret have been favored for research on cortical mechanisms of sound localization because those species have well-developed auditory cortices and because, as nocturnal predators, they have evolved accurate sound-localization behavior. We focus on the cat and the ferret, summarizing results from nonhuman primates at the end of the section.

3.46.2.1 Spatial Receptive Fields in the Primary Auditory Cortex

Early studies of the spatial sensitivity of neurons, perhaps inspired by visual cortical studies, attempted to map the borders of spatial receptive fields of neurons. Evans E. F. (1967) reported that the majority of the neurons in his sample showed a preference for the location of a handheld transient sound source and that the majority of spatially sensitive neurons preferred sound sources located on the side contralateral to the recorded cortical hemisphere. Similarly, Eisenman L. M. (1974) found a mixture of spatially sensitive and insensitive neurons, with most of the spatially sensitive neurons responding best to sounds at contralateral locations. Middlebrooks J. C. and Pettigrew J. D. (1981) mapped receptive fields using pure tones presented from a movable loudspeaker in an anechoic chamber. Stimulus levels were 10 dB above each neuron's threshold; additional levels were tested in some cases. About half of the neurons were classified as omnidirectional because they responded with at least occasional spikes to sound sources located anywhere within the 180° arc tested in front of the cat. The remaining neurons had hemifield or axial receptive fields. The hemifield receptive fields encompassed most locations contralateral to

the recording site and had borders coinciding approximately with the vertical midline. Axial receptive fields were contained entirely within the frontal contralateral quadrant of space and were centered on the acoustic axis of the pinna on the side contralateral to the recording site. The acoustic axis was defined in that study as the direction for which the pinna contributed the maximum acoustic gain at any particular frequency. Neurons with hemifield receptive fields tended to have characteristic frequencies below 12 kHz, and neurons with axial receptive fields typically were tuned to frequencies above 12 kHz. In later experiments using broadband sound sources and higher sound levels, described below, the various receptive field classes have been less distinct, tending to form a continuum from axial, through hemifield, to omnidirectional depending on the stimulus level and bandwidth and on the characteristics of particular neurons.

The results of the Middlebrooks J. C. and Pettigrew J. D. (1981) study illustrated the importance of the passive directionality of the head and external ears in shaping the directional sensitivity of cortical neurons. In that study, for example, the centers of axial receptive fields tended to vary among cats according to how the contralateral pinna was positioned, and deflection of the contralateral pinna resulted in a shift of the locations of cortical spatial receptive fields. In subsequent studies that tested multiple sound levels, sharply bounded axial receptive fields have been evident only at stimulus levels within ~10 dB of neural thresholds (Imig, T. J. *et al.*, 1990; Rajan, R. *et al.*, 1990b). Nevertheless, the imprint of pinna acoustics on spatial receptive fields is evident at levels as high as 50 dB above neural thresholds (Brugge, J. F. *et al.*, 1996; Reale, R. A. *et al.*, 2003). That most auditory spatial receptive fields are centered in front of one or the other pinna is a conspicuous difference in comparison with receptive fields in the visual and somatosensory systems. That issue will be considered further in Section 3.46.2.3.

Several groups have quantified spike rates of neurons in cat area A1 (primary auditory cortex) as a function of sound-source azimuth (i.e., the location in the horizontal dimension) and sound level (Imig, T. J. *et al.*, 1990; Rajan, R. *et al.*, 1990b; Poirier, P. *et al.*, 1997; Eggermont, J. J. and Mossop, J. E., 1998; Middlebrooks, J. C. *et al.*, 1998). As in previous qualitative studies, the distribution of spatial tuning among neurons was dominated by contralateral preferred locations. Nevertheless, a sizable number of neurons responded preferentially to sound sources near the frontal midline (17% in Imig, T. J. *et al.*, 1990) and to sources located on the ipsilateral side (23% in Imig, T. J. *et al.*, 1990). Figure 1 shows examples of an ipsilaterally tuned neuron (Figure 1(a)), a midline neuron (Figure 1(b)), and two contralaterally tuned neurons (Figures 1(c) and 1(d)). Spatial receptive fields tend to grow in size to varying degrees with increasing sound level. Rajan R. *et al.* (1990b), for instance, reported that 60% of spatially selective neurons showed receptive field borders that were constant across a 20–40 dB range of sound levels. Imig T. J. *et al.* (1990), in contrast, reported that the spatial sensitivity of only a minority of their sample was level invariant over a 40–60 dB range.

Virtual auditory space technology has been applied in several experiments for study of spatial sensitivity of neurons (e.g., Brugge, J. F. *et al.*, 1994; 1996; Mrsic-Flogel, T. D. *et al.*, 2001; 2003; 2005). In that approach, broadband sounds are presented sequentially at many locations around an animal, and the resulting sounds are recorded with miniature microphones placed in the animal's ear canals, thus capturing the direction-dependent transfer functions (DTFs) of the external ear. In a later step, arbitrary test stimuli (usually clicks or noise bursts) are filtered by the DTFs and presented to the animal's ears through sealed earphones while recording spike activity from the auditory cortex or other neural structure. The virtual auditory space technique facilitates rapid mapping of spatial sensitivity in azimuth and elevation. The majority of neurons studied with virtual auditory space techniques show receptive fields that are restricted to the contra- or ipsilateral frontal quadrant of space for sound levels no more than ~30 dB above neural thresholds. At those levels, the spatial medians of receptive fields tend to coincide with the acoustic axis of one or the other pinna. At higher sound levels, receptive fields tend to broaden, often expanding to encompass all tested locations.

Cortical neurons tend to demonstrate spatial sensitivity not only in terms of their response magnitude (i.e., their spike counts or spike probabilities) but in terms of the latencies of spikes (e.g., Middlebrooks, J. C. *et al.*, 1994; Brugge, J. F. *et al.*, 1996; Middlebrooks, J. C. *et al.*, 1998; Jenison, R. L. *et al.*, 2000; Furukawa, S. and Middlebrooks, J. C., 2002; Reale, R. A. *et al.*, 2003; Stecker, G. C. and Middlebrooks, J. C., 2003). Generally, first-spike latencies vary inversely with spike counts: sounds at preferred locations tend to elicit more spikes with shorter latencies. In some instances, however, spike latencies can show modulation by sound-source location even at high sound levels at which neurons respond with high probability to sounds at all tested locations (Reale, R. A. *et al.*, 2003). An example of spatial gradients of first-spike latencies for a neuron in cat A1 is shown in Figure 2.

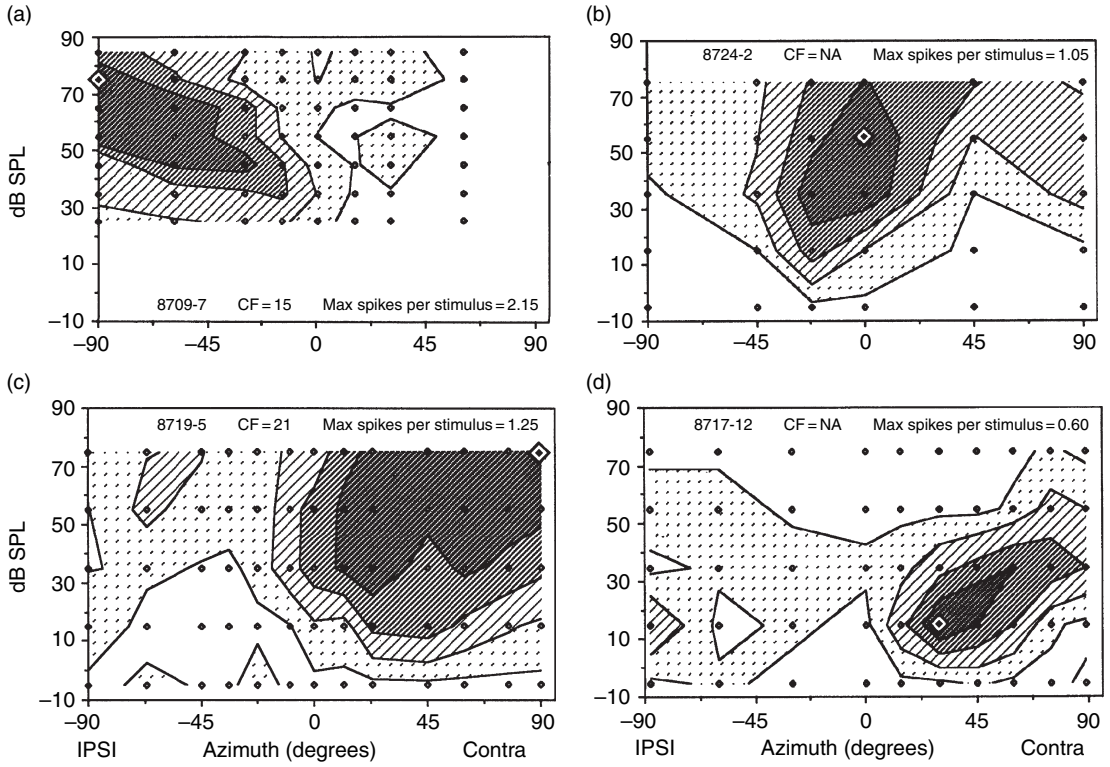

Figure 1 Spatial sensitivity of four neurons in cat area A1. In each panel, contours represent normalized spike rates as a function of sound-source azimuth (horizontal axes) and sound level (vertical axes). Contours are drawn at 5%, 25%, 50%, and 75% of maximum spike rates. The grids of small diamonds indicate stimulus locations and levels that were tested. Reproduced from Imig, T. J., Irons, W. A., and Samson, F. R. 1990. Single-unit selectivity to azimuthal direction and sound pressure level of noise bursts in cat high-frequency primary auditory cortex. J. Neurophysiol. 63, 1448–1466, used with permission from the American Physiological Society.

3.46.2.2 Spatial Sensitivity Outside Area A1

Figure 3 shows the locations of auditory cortical fields on a lateral view of the cat brain. Early studies of spatial sensitivity focused on cortical area A1, perhaps because of its central position in distributing information to other cortical area and because of demonstrations that experimental lesions in A1 result in localization deficits (e.g., Jenkins, W. M. and Merzenich, M. M., 1984). Several more-recent studies have searched beyond the bounds of A1 with the goal of identifying areas that might show enhanced spatial sensitivity. The first such studies examined two nontonotopic areas, areas AES (anterior ectosylvian nuclear area) and A2 (second auditory cortex) (Middlebrooks, J. C. *et al.*, 1994; 1998). These are auditory cortical areas in which neurons show broad frequency tuning and robust responses to broadband sounds and in which there is little or no evidence for tonotopic representation of frequency. Perceptual studies of sound localization demonstrate that localization is enhanced by broadband stimuli (reviewed by Middlebrooks, J. C. and Green, D. M., 1991), presumably indicating that listeners make effective use of location cues across multiple frequencies. The broad frequency tuning of neurons in the nontonotopic cortical areas might reflect a neural substrate for integration of multiple location cues. For that reason, the nontonotopic cortical areas might seem like a logical place to look for enhanced spatial sensitivity. Also, area AES projects to the deep layers of the superior colliculus (Meredith, M. A. and Clemo, H. R., 1989), which is known to contain a topographic map of auditory space (Middlebrooks, J. C. and Knudsen, E. I., 1984).

Despite the *a priori* speculation that areas AES and A2 might show enhanced spatial sensitivity compared with area A1, the spatial sensitivity observed in those nontonotopic areas was qualitatively similar to that observed in A1 (Middlebrooks, J. C. *et al.*, 1994; 1998; Xu, L. *et al.*, 1998; Furukawa, S. *et al.*, 2000). As in area A1, spatial receptive fields tended to broaden as sound levels were increased. Middlebrooks J. C. *et al.* (1998)

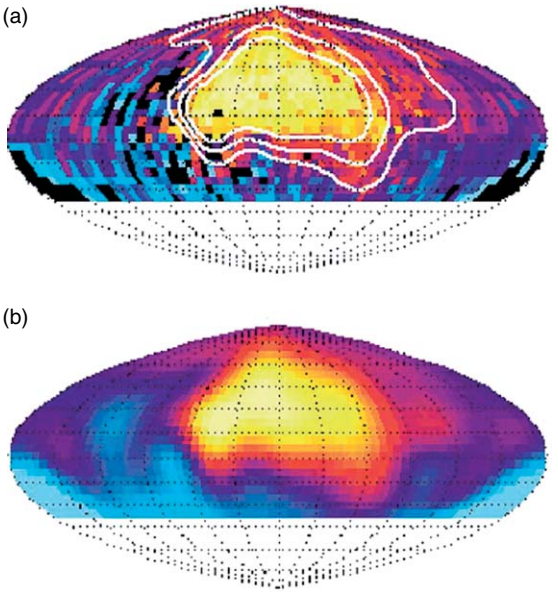

Figure 2 Spatial sensitivity of latencies for a neuron in cat area A1. Transient sounds were presented in virtual auditory space. Latency varied from 11.0 ms (yellow) to 15.0 ms (blue) as a function of virtual source location. Solid white contours are isolatency contours. These quartic authalic (equal-area) projections represent 360° of auditory space. The central vertical meridian represents the vertical midline. (a) Measured data. (b) The data from Figure 1(a) modeled as a linear combination of von Mises basis functions. Reproduced from Brugge, J. F., Reale, R. A., Jenison, R. L., and Schnupp, J. 2001. Auditory cortical spatial receptive fields. Audiol. Neurootol. 6, 173–177, with permission from S. Karger A G, Basel.

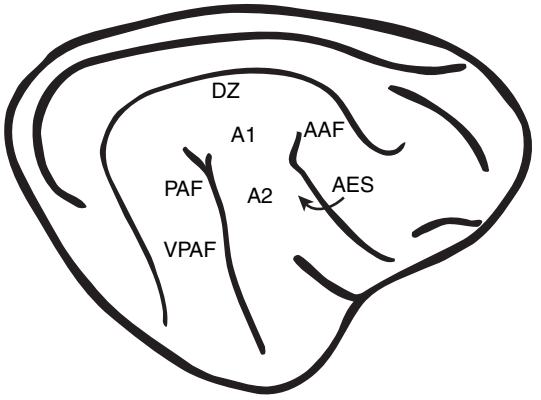

Figure 3 Lateral view of the cat brain. The following auditory areas are shown: primary auditory cortex (A1), dorsal zone of A1 (DZ), second auditory cortex (A2), anterior auditory field (AAF), anterior ectosylvian sulcus auditory area (AES), posterior auditory field (PAF), and ventral posterior auditory field (VPAF).

represented the preferred azimuths of neurons by their centroids, defined as the spike-count-weighted centers of mass of their spike-count-versus-azimuth functions. As in area A1, the centroids of the substantial majority of neurons lay in the frontal contralateral quadrant of space, near the acoustic axis of the contralateral pinna. Quantitatively, spatial sensitivity in AES and A2 appeared somewhat greater than in A1, although no direct comparison was made. Spike counts of the majority of neurons recorded in AES and A2 were modulated by >50% by changes in sound-source azimuth. Spatial tuning generally was broad in that, at sound levels >20 dB above neural thresholds, most receptive fields spanned >180° of azimuth. Although failing to demonstrate especially sharp receptive field borders in AES and A2, those studies were the first to demonstrate that spike patterns of neurons varied systematically as a function of sound-source location throughout those large receptive fields, resulting in an effectively panoramic representation of sound locations. That issue is considered further in Section 3.46.3.1.

Area A1 is surrounded by several other auditory cortical areas that are more or less tonotopically organized, including the anterior auditory field (AAF), the dorsal zone of A1 (DZ), and the posterior auditory field (PAF) (e.g., Reale, R. A. and Imig, T. J., 1980; Middlebrooks, J. C. and Zook, J. M., 1983). Recent studies of area AAF indicate that neurons there have spatial sensitivity similar to that of A1 neurons but that AAF neurons tend to show greater broadening of spatial receptive fields in response to increasing sound levels (Harrington, I. A. *et al.*, 2005). Areas DZ and PAF, however, have several features that, *a priori*, make them attractive places to search for enhanced spatial sensitivity. Area DZ was described as a band of cortex dorsal to A1 proper in which frequency tuning was conspicuously broader than in A1 and shifted somewhat to higher frequencies (Middlebrooks, J. C. and Zook, J. M., 1983). Also, in closed-field stimulus conditions, many neurons in DZ failed to respond to either ear alone but showed a strongly facilitated response to equal sounds at the two ears. That binaural response property appeared predictive of sensitivity for free-field sounds located near the midline. Area PAF has been described as having many neurons that show nonmonotonic spike-count-versus-level functions (Phillips, D. P. and Orman, S. S., 1984; Phillips, D. P. *et al.*, 1995). Nonmonotonicity is pertinent to spatial sensitivity because Imig T. J. *et al.* (1990) reported that the most spatially sensitive neurons in A1 also tended to show nonmonotonic level sensitivity. Also, neurons in PAF tend to show rather complex

frequency response areas (Loftus, W. C. and Sutter, M. L., 2001), which might reflect a sensitivity to spectral cues for sound localization.

Recordings in PAF and DZ confirmed the speculation that neurons in those areas might show enhanced spatial sensitivity (Stecker, G. C. *et al.*, 2003; 2005a). Qualitatively, there were no spatial properties that had not been seen at least in milder form in A1 (i.e., no topographic space map; no pin-point receptive fields). Nevertheless, PAF and DZ showed several quantitative differences compared with A1. Figure 4 shows examples of responses in DZ, PAF, and A1. The left column shows frequency response areas, with the typical V-shaped frequency tuning in A1 and more complex multipeaked frequency tuning in DZ and PAF. Spatial sensitivity is represented by rasters (second column) and rate-versus-azimuth functions (third column). The confusion matrices in the fourth column will be discussed in Section 3.46.3. Compared to those in area A1 (and to areas AES and A2, not shown), spike counts in PAF and DZ were modulated more strongly by sound-source location, spatial gradients were sharper, and (particularly in PAF) spatial tuning was less sensitive to changes in stimulus level. A striking finding in PAF, and to a lesser degree in DZ, was the degree of modulation of spike latencies by sound-source location. Median first-spike latencies were longer in PAF than in A1 (PAF 28.8 ms, DZ 22.0 ms, A1 17.6 ms), and the range of latencies resulting from changes in sound-source azimuth was substantially larger (median ranges: PAF 10.6 ms, DZ 8.4 ms, A1 3.1 ms). The difference between PAF and A1 in the dependence of latency on sound-source location suggests that an intracortical mechanism, as yet unidentified, might act to recode stimulus location as response latency.

3.46.2.3 Spatial Topography

Studies of spatial sensitivity in the auditory cortex consistently have failed to identify a point-to-point map of sound-source location onto cortical place. A point-to-point map would require, first, that the locations of spatial receptive fields vary continuously among neurons and, second, that receptive fields of neurons vary as a function of locations of neurons on the cortex. The first condition is largely unmet, so the second condition is moot. That is, as described above, the distribution of receptive field centroids among neurons is markedly nonuniform, with the majority of centroids located near the axis of one or the other pinna and little coverage of locations across the frontal midline. Regarding the distribution of neurons in the cortex, in A1 one can identify cortical regions on a scale of one to a few millimeters in which neurons all tend to show similar response properties, but the transition from one such region to another is abrupt (Middlebrooks, J. C. and Pettigrew, J. D., 1981; Imig, T. J. *et al.*, 1990; Rajan, R. *et al.*, 1990a; Clarey *et al.*, 1994). In AES, a quantitative test showed that there is a significant tendency of nearby neurons to have nearby receptive field locations, but there was no indication of a continuous space map (Middlebrooks, J. C. *et al.*, 1998). In DZ, there is somewhat more uniform coverage of azimuth by the distribution of centroids compared to A1 and PAF, especially a larger number of midline and ipsilaterally tuned neurons (Stecker, G. C. *et al.*, 2005a). One can find examples in DZ of sequences of neurons that show progressive shifts in centroid locations. Such sequences are the exception rather than the rule, however, and the sequences tend to terminate with abrupt shifts in centroid location. To summarize, there is no convincing evidence that auditory space is represented in the form of a point-to-point map. Instead, the data are more consistent with a highly distributed representation, as discussed in Section 3.46.3.

3.46.2.4 Spatial Sensitivity in Unanesthetized Cats

By far, the majority of previous studies of spatial sensitivity have been conducted in anesthetized animals. The use of general anesthesia almost certainly has an impact on the response patterns and on the stimulus sensitivity of cortical neurons. For that reason, there is a growing interest in cortical studies in awake animals. Mickey B. J. and Middlebrooks J. C. (2003; 2005) have used a preparation in which 16-site recording probes are implanted chronically in area A1 of cats. The cat is trained to listen to broadband noise bursts that vary in location and to release a pedal when the sound changes from a noise burst to a 200 Hz pulse train. The activity of single units and multiunit clusters is recorded simultaneously from the 16 cortical sites.

The results from recordings in area A1 in awake cats agree with the major points of the previous studies that used anesthesia. That is, spatial tuning of single neurons generally is broad, and there is no evidence for point-to-point spatial topography. Beyond that general agreement, however, the responses of neurons in the unanesthetized condition are strikingly different from those in the anesthetized condition. Examples of raster plots are shown in Figure 5. In anesthetized cats, nearly all neurons tend to respond with a burst of spikes at the onset of the sound and no continuing (tonic) response

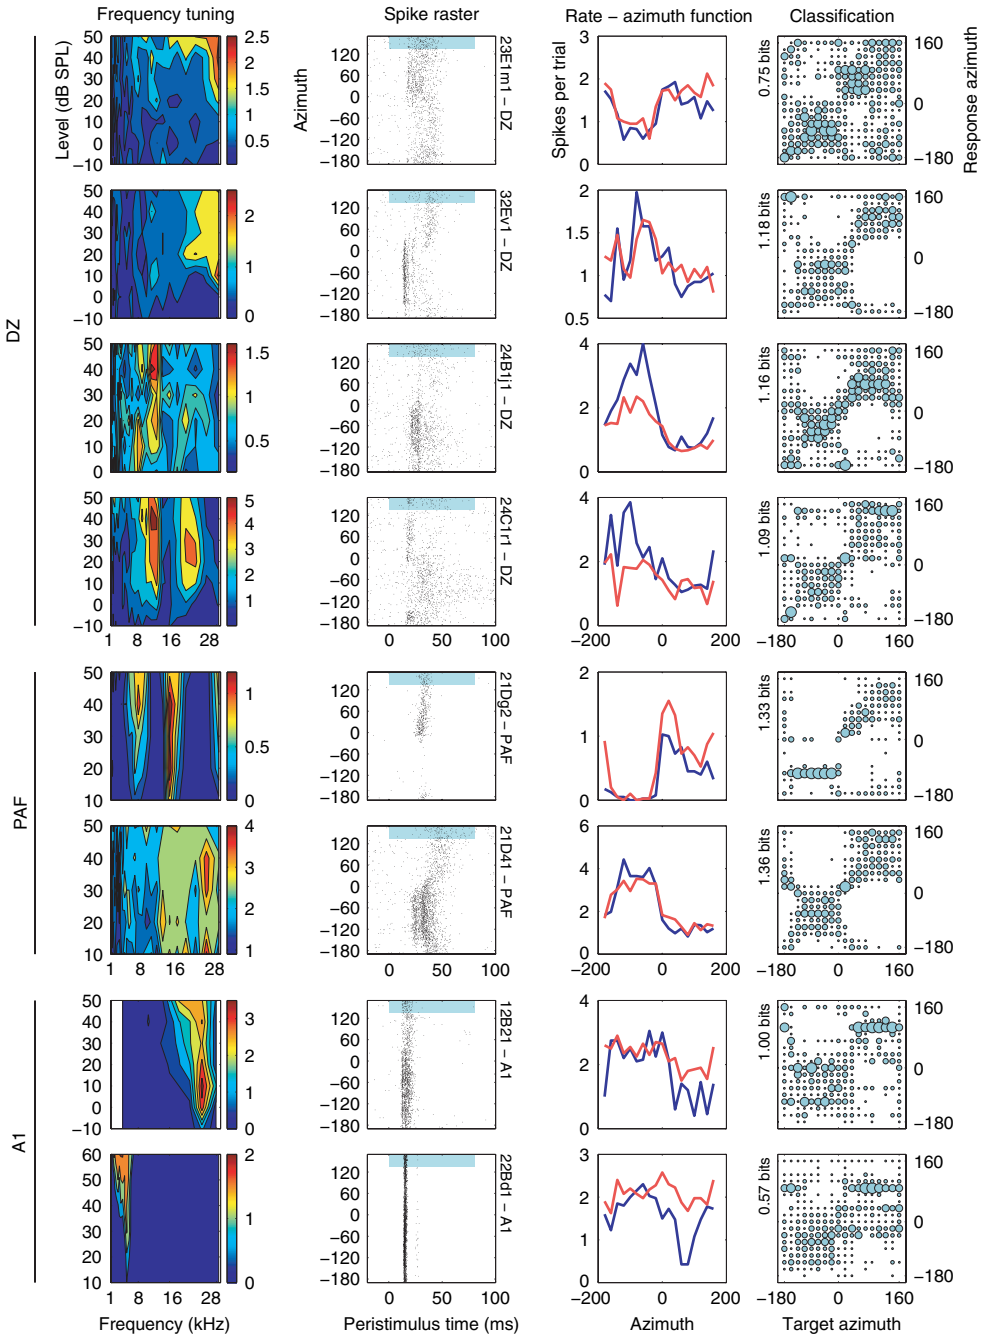

Figure 4 Examples of neural responses in cat dorsal zone of A1 (DZ), posterior auditory field (PAF), and primary auditory cortex (A1). First column: Frequency–response areas plot mean spike count as a function of stimulus frequency (horizontal axes) and level (vertical axes). Color bars indicate spikes per trial. Second column: Raster plots showing spatial sensitivity as a function of sound-source location (vertical axes). Each row of dots represents spikes resulting from one stimulus presentation. Ten repetitions are shown for each location. Time is represented on the horizontal axes. Blue shading indicates the stimulus duration. Third column: Mean spike rate sound as a function of sound-source location. Blue and red lines represent sound levels 20 and 40 dB, respectively, about neural thresholds. Fourth column: Joint stimulus–probability matrices (confusion matrices) show the accuracy of localization by neural spike patterns, as described in the text. The area of each symbol represents the proportion of trials in which a particular estimated azimuth (vertical axis) was given in response to a particular actual stimulus location (horizontal axis). Transmitted information rates computed from each matrix are given along the left axis. Reproduced from Stecker, G. C., Harrington, I. A., Macpherson, E. A., and Middlebrooks, J. C. 2005a. Spatial sensitivity in the dorsal zone (area DZ) of cat auditory cortex. J. Neurophysiol. 94, 1267–1280, used with permission from the American Physiological Society.

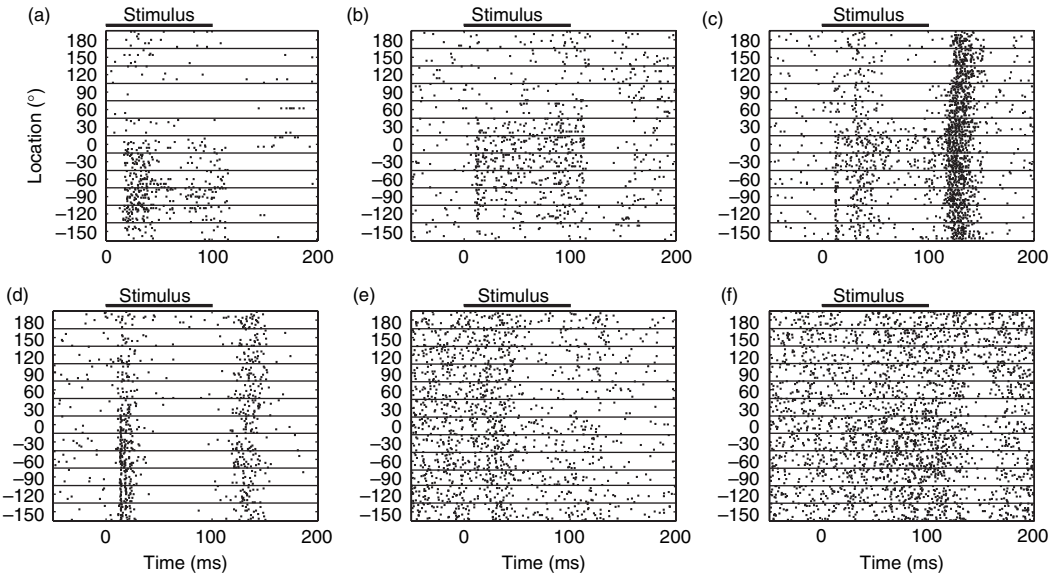

Figure 5 Spatial sensitivity of six neurons in area A1 of the awake cat. Rasters represent responses to 10 stimulus repetitions at each sound-source azimuth. The stimulus duration is given by the bar at the top of each panel. Reproduced from Mickey, B. J. and Middlebrooks, J. C. 2003. Representation of auditory space by cortical neurons in awake cats. J. Neurosci. 23, 8649–8663, with permission from the Society for Neurosciences.

(Figure 4, bottom 2 rows). In contrast, the neurons in awake animals (Figure 5) show a diversity of temporal response patterns, including onset bursts, bursts at stimulus offset, tonic responses, stimulus-related inhibition of spontaneous activity, and combinations of those patterns that vary according to stimulus location. Spatial tuning is sharper, partially due to the presence of suppression of background activity by stimuli at nonoptimal locations. Spatial sensitivity is appreciably less vulnerable to changes in sound level. Also in contrast to the anesthetized condition, the peaks of azimuth functions are distributed fairly uniformly throughout the contralateral half of space. These early results from an awake preparation offer the promise of a wealth of new understanding of spatial sensitivity of auditory cortical neurons.

3.46.2.5 Dynamic Spatial Sensitivity

The sensitivity of a cortical neural to the location of a particular sound can be influenced by preceding sounds. In this section, we will discuss effects of changes in stimulus location, more or less related to motion sensitivity. In the following section, we will consider cortical responses to pairs of sounds that could result from direct and reflected paths to the ear.

Research on the motion sensitivity of cortical neurons has been hampered by the difficulty of presenting controlled moving sound sources without introducing other extraneous sounds. One solution has been to use simulated sound motion produced by sequential activation of a series of sound sources located along some particular trajectory. Using such a technique, Poirier P. *et al.* (1997) showed that about a quarter of neurons sampled in area A1 showed direction sensitivity in the sense that their spike rate was two or more times greater for a sound moving in one direction than the same sound moving in the opposite direction. A larger proportion of neurons (88%) showed such behavior in area AES (Jiang, H. *et al.*, 2000).

A study of low-frequency neurons in area A1 of awake monkeys demonstrated dynamic sensitivity to interaural phase differences (IPDs) that could be taken as indicative of motion selectivity (Malone, B. J. *et al.*, 2002). The response of a particular neuron to a particular static IPD varied according to the IPD of a preceding sound, and the IPD of a preceding sound influenced the IPD that produced the strongest response. Moreover, neurons often showed selectivity for the direction of changing IPD, analogous to selectivity for the direction of azimuthal motion of a low-frequency sound source.

Jenison R. L. *et al.* (2001) used a form of spatial white-noise analysis to study the dynamic spatial sensitivity of neurons in area A1. Identical 10 ms noise bursts were presented from random locations in virtual

auditory space, and space–time receptive fields were computed by compiling the source locations that preceded spikes of cortical neurons. Some 14% of neurons showed receptive fields that were inseparable in that their dynamic space–time receptive fields could not be separated into independent spatial and temporal components. That is, the spatial sensitivity of a neuron at any particular time was influenced by the locations of previous sounds. This implies that neurons are sensitive to the speed and direction of sound motion. Such motion sensitivity was confirmed in tests using simulated motion trajectories.

There is some controversy in the human psychophysical literature regarding the existence of specific motion detectors in the auditory system. One possibility is that neurons in the auditory system might show motion sensitivity analogous to the motion sensitivity that is evident in the visual system. An alternative to a specific auditory motion representation would be that auditory motion is represented only in the comparison of static snapshots of the changing stimulus location (reviews: Middlebrooks, J. C. and Green, D. M., 1991; Grantham, D. W., 1997). A previous review stated: "As yet there is no compelling evidence for motion-sensitive systems in the auditory system" (Middlebrooks, J. C. and Green, D. M., 1991). Subsequent to that review, functional brain imaging has been applied to the problem, but the evidence is so far equivocal. A number of studies have found that moving stimuli activate bilateral loci in the temporal lobe (e.g., Baumgart, F. *et al.*, 1999) and in the right parietal lobe (e.g., Griffiths, T. *et al.*, 1998). The same areas, however, are activated equally well by stationary stimuli that vary randomly in spatial location (Smith, A. L. *et al.*, 2004). It is possible that these cortical areas contain both location-sensitive and motion-sensitive cells intermingled at a scale that cannot be resolved by current imaging methods.

The results discussed above from animal cortical studies showing dynamic spatial sensitivity in addition to recent psychophysical results tend to tip the balance more in favor of motion-sensitive systems. Psychophysical evidence suggests that sensitivity to source motion at relatively low velocities ($<60^\circ\ s^{-1}$) enhances the discrimination of source velocity beyond that observed when only endpoint displacement information is available, although listeners also make use of displacement cues if they are available (Grantham, D. W., 1997; Carlile, S. and Best, V., 2002). Auditory motion adaptation and aftereffect phenomena also suggest the existence of specialized motion detectors (Grantham, D. W. and Wightman, F. L., 1979; Dong, C. J. *et al.*, 1999; Neelon, M. F. and Jenison, R. L., 2004).

3.46.2.6 Multiple Sound Sources

In a typical natural environment, a listener must localize sounds in a background of other sounds and must distinguish the actual location of a sound source from multiple reflective surfaces. Several groups have begun to explore the spatial sensitivity of cortical neurons in the presence of continuous background sounds and sensitivity to the locations of leading and lagging pairs of sounds.

Brugge J. F. *et al.* (1998) examined the effect of continuous background noise on the spatial sensitivity of neurons on cat A1. Stimuli were presented in virtual auditory space, and uncorrelated noise at the two ears produced a spatially diffuse background. In the absence of a noise background, spatial receptive fields mapped with transient signals were large, typically occupying a quadrant or more of virtual auditory space. Within those large receptive fields, first-spike latencies formed functional gradients – typically, latencies were shortest for stimuli near the acoustic axis of the contralateral ear and increased with increasing separation from the axis. Introduction of background noise reduced spike counts and increased latencies throughout the receptive field, but the general structure of the receptive field, including the latency gradients, was preserved. That is, increasing the level of a background noise was largely equivalent to decreasing the level of the signal.

Furukawa S. and Middlebrooks J. C. (2001) performed a similar experiment, differing in that the stimuli were presented in a free sound field and the recordings were from area A2. In a condition of diffuse background noise, the result was the same as that obtained by Brugge J. F. *et al.* (1998). Increasing the background noise level simply decreased the effective level of the stimulus such that spike rates were reduced and spatial receptive fields narrowed. A very different result was obtained when the background noise was presented from a discrete location in the free field. In that condition, the background noise tended to mask the signal differentially according to masker location, the masking being greatest when the masker was located near the signal. That means that a masker placed at the centroid of a neuron located near the axis of the contralateral ear could suppress the response to sounds at the contralateral axis, thereby deflecting the centroid toward the axis of the ipsilateral ear. In conditions in which the spatial sensitivity of a neuron in quiet was nearly omnidirectional, the introduction of a focal background noise could suppress responses to signals

near the masker and effectively carve out a rather restricted receptive field. These results from neurons in cat area A2 are analogous to psychophysical demonstrations of spatial unmasking, in which detection of a signal in noise is enhanced by moving the signal away from the masker (Terhune, J. M. and Turnbull, S. D., 1989; Saberi, K. *et al.*, 1991). There are no analogous psychophysical demonstrations, however, suggesting that a focal continuous noise source can produce a systematic deflection of the spatial judgment of a target (Good, M. D. and Gilkey, R. H., 1996; 1997; Lorenzi, C. *et al.*, 1999).

Pairs of sounds separated in time produce in human listeners a variety of spatial percepts that differ according to the interstimulus delay (ISD). Those phenomena are referred to collectively as the precedence effect (reviewed by Litovsky, R. Y. *et al.*, 1999). Physiological analogs to those perceptual phenomena have been observed in the spatial sensitivity of cortical units. When the ISD is less than ~1 ms, a human listener will report a single auditory event that is located at a point intermediate between the two sources, biased toward the earlier source. This is summing localization. Mickey B. J. and Middlebrooks J. C. (2001) recorded responses of neurons in cat areas A1 and A2 to sound pairs that produce summing localization. They used a computer pattern-recognition algorithm to identify cortical spike patterns associated with particular locations, thus attempting to recognize the locations signaled by neurons (discussed further in Section 3.46.3). Locations recorded in that way closely followed predictions of summing localization. That is, a 1 ms ISD produced responses signaling the location of the leading stimulus, 0 ms ISDs produced responses signaling the location midway between the two sound sources, and ISDs between 0 and 1 ms produced responses signaling locations biased toward the leading source in proportion to the magnitude of the ISD.

When human listeners are presented with pairs of sounds separated by ~1–4 ms, their localization judgment is dominated by the location of the leading sound. Cortical physiology results in awake rabbits (Fitzpatrick, D. C. *et al.*, 1999) and awake or anesthetized cats (Mickey, B. J. and Middlebrooks, J. C. 2001; 2005) accord with that phenomenon in that most neurons fail to respond at all to sounds that lag a leading sound by several milliseconds. Differences between human psychophysics and animal cortical physiology appear in the ISD range of five to a few hundred milliseconds. A human listener normally can detect a lagging sound after ~5 ms and can begin to localize the lagging sound with some accuracy after ~10 ms. In contrast, the animal cortical data show that many neurons still are strongly suppressed during that time range. In a study of area A1 in the awake rabbit, for instance, the median time for 50% recovery of mean spike counts was 21.9 ms, and some neurons showed suppression out to ~300 ms (Fitzpatrick, D. C. *et al.*, 1999). In area A1 of the anesthetized cat (Reale, R. A. and Brugge, J. F., 2000), responses to lagging sounds were suppressed over an ISD range of 50–200 ms. Despite the suppression of responses to lagging sounds, however, the spatial sensitivity of neurons in that study (mapped with virtual auditory space techniques) was largely preserved. That is, spatial receptive fields of many neurons in the presence of a sound leading by 100–400 ms resembled receptive fields mapped in control conditions using a lower sound level. Similarly, spatial gradients of first-spike latencies were largely preserved.

In areas A1, A2, and PAF of anesthetized cats, most neurons responded to a leading sound with a burst of spikes followed by a period of suppression lasting 100–200 ms (Mickey, B. J. and Middlebrooks, J. C., 2005). A period of suppression also was seen in awake cats, although the recovery was somewhat faster (Mickey, B. J. and Middlebrooks, J. C., 2005). Only 12% of neurons showed discrete responses to lagging sounds at ISDs of 20 ms, a delay at which human listeners can readily detect and localize a lagging sound. In the ISD range of 1–16 ms, most neurons transmitted considerable information about the location of a leading sound, analogous to performance by human listeners. In contrast with the ability of human listeners to localize sounds at ISDs of 8–16 ms (Yang, X. and Grantham, D. W., 1997), however, there was little information transmitted in the cat cortical spike patterns about the location of the lagging sound. That is, although Reale R. A. and Brugge J. F. (2000) showed that spatial sensitivity is present at long ISDs, there is as yet no evidence for cortical coding of the locations of lagging sounds over a range of delays at which human listeners localize quite accurately.

3.46.2.7 Acoustic Basis for Spatial Sensitivity

The location of a sound source is not mapped directly at the auditory periphery but must be computed based on multiple cues provided by the interaction of the incident sound wave with the

head and external ears. Cortical neurons are well known to be sensitive to one or both of the major cues for azimuth, interaural level differences and interaural time differences. We refer the reader to other recent sources for reviews of the large literature on interaural difference sensitivity in the auditory cortex (Fitzpatrick, D. C. *et al.*, 2000; Zhang, J. *et al.*, 2004). We focus in this review on several studies that have related neuronal spatial sensitivity to the frequency sensitivity of neurons combined with the directional acoustics of the periphery.

The use of virtual auditory space techniques makes it possible to, in effect, exchange the external ear acoustics of one animal for another. That is, one can record the responses of cortical neurons in one animal to stimuli filtered with DTFs measured from another animal. For instance, Mrsic-Flogel T. D. *et al.* (2001) demonstrated that 73% of neurons studied in area A1 of the ferret showed significant changes in the shape or location of spatial receptive fields when stimulated with DTFs measured from another ferret. This approach has been used to explore the development of spatial sensitivity in the cortex (Mrsic-Flogel, T. D. *et al.*, 2003). Cortical neurons in immature ferrets (postnatal age 33–39 days) tend to be broader and to carry less information about stimulus location than do neurons in adult ferrets. When neurons in immature ferrets are tested with stimuli filtered with DTFs from mature ferrets, the spatial sensitivity sharpens. This implies that the relatively poor spatial sensitivity of cortical neurons in immature ferrets is determined by the small size and lack of development of physical structures of the head and external ears more than by immaturity of neural pathways.

Human listeners make systematic errors in vertical localization when presented with sounds that have been processed with a narrowband filter (Middlebrooks, J. C., 1992). It was hypothesized that the narrowband filter mimics an aspect of the directional filter properties of the external ears. That hypothesis was supported by a computational model that predicted localization judgments on the basis of correlation of the narrowband filter shape with the DTFs of individual listeners. An analogous procedure was tested in the cat, using recordings of neurons in area A2. The elevation sensitivity of neurons was measured using broadband and narrowband sounds presented in a free field. When tested with narrowband sounds, neural responses tended to signal particular elevations that depended on the center frequency of the stimulus, not on the actual location of the source. The computational model from the human study (Middlebrooks, J. C., 1992) was adapted to cats by applying DTFs of individual cat's ears. That model could effectively predict the spatial sensitivity of the cortical neurons, indicating a straightforward relationship between external ear acoustics and elevation sensitivity.

Schnupp J. W. H. and colleagues (Schnupp J. W. H. *et al.*, 2001; Mrsic-Flogel, T. D. *et al.*, 2005) attempted to account for the spatial sensitivity of neurons in area A1 of ferrets on the basis of a linear combination of the frequency sensitivity of the two ears and the directional acoustics of the auditory periphery. Frequency–time response fields (FTRFs) were measured using a reverse correlation analysis of responses to multiple random-frequency tone pips presented to the two ears. The FTRFs captured the frequency-dependent excitatory and inhibitory contributions of each ear. Sensitivity to interaural level differences presumably was captured by the use of stimulus sets presented simultaneously to the two ears, but sensitivity of neurons to interaural differences in temporal fine structure (i.e., IPD sensitivity) was not captured. The FTRF for each ear was multiplied by the DTF of that ear, yielding an estimate of the directional sensitivity of neuronal responses. The estimates of spatial receptive fields provided by this simple model were remarkably good for the majority of high-frequency neurons, which were said to exhibit linear processing of spatial cues. For many neurons, the procedure could estimate the growth of spatial receptive fields with increasing sound pressure level, although that estimation was more successful for neurons that receive predominantly excitatory input from the contralateral ear and inhibitory input from the ipsilateral ear (EI neurons) than for neurons that derive predominantly excitatory input from both ears (EE neurons). Performance was less satisfactory for low-frequency neurons that, presumably, derive spatial sensitivity largely from IPD cues. Also, the linear estimation procedure failed to duplicate the location dependence of first-spike latencies that commonly is observed in empirical data.

Macpherson E. A. *et al.* (2004) applied a similar linear estimation procedure to characterize elevation sensitivity of several auditory cortical fields in cats. The elevation sensitivity of neurons in areas A1 and AAF was predicted accurately by a simple linear model, but the linear model worked poorly for neurons in areas DZ and PAF. One possible explanation for those results is that neurons in DZ and PAF exhibit

greater nonlinearity than do A1 and AAF neurons, perhaps reflecting greater nonlinearity in the processes within DZ and PAF or indicating that nonlinear processes are added on in a projection from A1 to DZ and PAF. A second possibility is that spatial sensitivity in all fields incorporates similarly nonlinear processing but that the nonlinearity is not as evident in A1 and AAF neurons because those neurons tend to show relatively narrow frequency tuning.

3.46.2.8 Nonhuman Primates

In nonhuman primates, spatial sensitivity of cortical neurons has been studied in temporal lobe auditory areas and in multimodal areas of the frontal and parietal cortex. We will focus on the auditory areas and refer the reader elsewhere for a brief overview of auditory spatial sensitivity in multimodal areas (Middlebrooks, J. C., 2000). Kaas J. H. and Hackett T. A. (Chapter 3.45) review the organization of the auditory areas in primates. Briefly, there is a core area containing two or more tonotopic representations; the core area in primates is homologous to region comprising areas A1, AAF, and PAF in the cat, although homologies among specific fields are unclear. The core area in primates is bordered by medial and lateral belt areas that, in turn, are bordered by parabelt areas.

In two early studies in unanesthetized macaques, stimuli were restricted to a limited number of locations in a frontal segment of the horizontal plane (Benson, D. A. *et al.*, 1981; Ahissar, M. *et al.*, 1992). Both studies showed that the majority of neurons in area A1 responded more strongly to contralateral than to ipsilateral sounds. The Benson group reported that neurons were more active when monkeys were engaged in an auditory task than when the monkeys were idle, but few neurons showed a significant difference in neuronal responses between a sound-localization task and a simple auditory detection task. The Ahissar group reported that some neurons showed a preference for a particular direction of sound-source motion, but those researchers declined to conclude that there were separate mechanisms for localization and for motion discrimination.

Recanzone G. H. *et al.* (2000) studied the spatial sensitivity of cortical neurons in awake behaving macaques. Recordings were from area A1 and from the caudomedial (CM) area of the medial belt region. Stimuli varied in azimuth and elevation, all within 30° of the origin at 0° azimuth, 0° elevation. Most neurons in A1 and CM showed a robust response across the entire tested area. The majority of neurons in A1 and CM were spatially tuned in the sense that regression analysis showed a significant correlation of spike count with stimulus azimuth and/or elevation. A statistical procedure was performed to determine the minimum change in sound-source location that could be detected on the basis of a change in the spike counts of single neurons. Those neuronal spatial discrimination thresholds were compared with analogous behavior thresholds from the same monkeys. Generally, the thresholds of CM neurons tended to correlate more closely with the behavioral thresholds than did those of A1 neurons.

Tian B. *et al.* (2001) compared spatial sensitivity among three of the lateral belt areas in anesthetized macaques: anterolateral (AL), middle lateral (ML), and caudolateral (CL). Stimuli were a selection of monkey calls presented in 20° steps of azimuth from −60° to +60° in the frontal horizontal plane. Based on histograms of spatial-tuning widths, it appears that the majority of neurons responded with at least half-maximal spike counts across more than half of the tested locations, with the half-maximum response area extending off one or both edges of the tested range. There was no indication of any striking qualitative difference in spatial sensitivity among the three tested cortical areas, but tuning widths in CL were significantly narrower than in AL and ML.

3.46.3 Reading the Location of a Sound Source from Patterns of Neural Activity

Studies of spatial sensitivity like those described above implicitly address the question: "Given this stimulus, what is the likely neuronal response?" A question that perhaps is more relevant to perception and behavior is: "Given this neuronal response, what was the most likely stimulus?" Research by several groups has begun to address this latter question, attempting to understand how response patterns of single cortical neurons or of neural populations could signal the location of a sound source.

3.46.3.1 Sound Localization by Single Neurons

Although many cortical neurons exhibit restricted spatial receptive fields at near-threshold sound levels, receptive fields measured at moderate sound levels

typically extend throughout 180° to 360° of azimuth. Nevertheless, even within an omnidirectional receptive field, the number and latency of spikes of a single neuron can vary systematically with sound-source location. Middlebrooks J. C. *et al.* (1994) adopted an artificial neural network as a spike-pattern classifier and attempted to estimate sound-source locations by recognizing sound-location-specific spike patterns of neurons in cortical area AES of anesthetized cats. That work demonstrated that the spike patterns of neurons could signal sound-source locations with variable amounts of accuracy throughout up to 360° of azimuth. This was referred to as panoramic location coding. The accuracy with which a computer-based classifier can estimate sound localization on the basis of neural spike patterns can be taken as a measure of the information contained with those spike patterns – information that presumably could contribute to an animal's perception and behavior.

Similar analysis has subsequently been applied to cortical areas A1 (Mickey, B. J. and Middlebrooks, J. C., 2001; 2003; Stecker, G. C. *et al.*, 2003), A2 (azimuth: (Middlebrooks, J. C. *et al.*, 1998); elevation: (Xu, L. *et al.*, 1998)), PAF (Stecker, G. C. *et al.*, 2003), DZ (Stecker, G. C. *et al.*, 2005a), and AAF (Harrington, I. A. *et al.*, 2005). There have been differences in the classifiers that have been used and in other details of analysis, but the general analysis procedure has been as follows. Spike patterns are recorded in response to multiple repetitions of sounds at multiple locations. The spike patterns are divided into 'training' and 'test' sets. The training set is used to train a computer-based classifier (typically a form of artificial neural network), then the trained classifier is used to estimate the sound-source location that elicited each pattern in the test set. For convenience in presentation, we will refer to this estimation of the sound-source location as sound localization by the cortical neuron. The localization performance of each neuron is assessed either with a measure of the magnitude of errors or by a measure of transmitted information (i.e., how much information about sound-source location is transmitted by the animal's auditory system to the recording electrode in the auditory cortex).

The rightmost column of Figure 4 shows examples of sound localization by neurons in areas A1, PAF, and DZ. Each panel shows a confusion matrix in which the area of each circle indicates the proportion of spike patterns that were localized to a particular estimated location (plotted on the vertical axis) in response to a stimulus at a particular target location (horizontal axis). Correct estimates of the target location fell on the major diagonal with positive slope; the DZ unit shown in the third row is an example with many correct estimates. Points lying on one of two minor diagonals with negative slope are instances in which the estimate of the lateral position was correct but in which front and back were confused; the PAF unit shown in the sixth row shows many such front/back confusions. We note that front/back confusions often are observed in human sound-localization judgments (e.g., Middlebrooks, J. C. and Green, D. M., 1991). In some instances, neurons discriminated left targets from right fairly accurately but could not discriminate locations within one hemifield; the A1 units in the bottom two rows are examples.

Qualitatively similar sound localization by single neurons has been observed in all auditory cortical areas in which this sort of analysis has been performed. That is, there is no indication that one area is doing something dramatically different from the others. Nevertheless, one can rank the localization performance of the areas, with areas A1 and AAF showing the least accuracy, areas AES and A2 intermediate, and areas DZ and PAF showing the most accurate localization. PAF in particular exhibits localization that is least vulnerable to changes in sound-source level.

As discussed in Section 3.46.2.3, the responses of neurons are not consistent with the existence of a topographic, point-to-point, map of auditory space. That is, one cannot identify particular neurons that are watching over particular sound-source locations. Instead, all the data are consistent with a highly distributed representation, in which each neuron transmits at least partial information about nearly all source locations and the representation of each source location is distributed among most of the auditory cortical population.

3.46.3.2 Information-Bearing Features of Spike Patterns

Cortical neurons exhibit spatial sensitivity both in terms of the magnitude of responses (i.e., spike count or spike probability) and in terms of the timing of spikes, as described in Section 3.46.2 and as is clearly evident in raster plots like those in Figure 4. Response magnitude is widely accepted in sensory neuroscience as representative of the response of a neuron to a particular stimulus. The pattern classification schemes used in studies discussed in Section

3.46.3.1 potentially exploit both magnitude and timing information. In this section, we consider the relative amounts of location-related information transmitted by response magnitude and timing.

The importance of cortical spike timing for location representation can be demonstrated by reducing spike patterns to simple spike counts, thus eliminating any temporal dimension of responses. Localization by classification of spike counts of neurons in areas AES and A2 was substantially inferior to that by spike patterns that preserved spike timing (Middlebrooks, J. C. *et al*., 1994; 1998). Furukawa S. and Middlebrooks J. C. (2002) quantified the amounts of location-related information that were transmitted by intact spike patterns of neurons in area A2 and by the same patterns degraded in one of two ways. In one condition, spike times were interchanged randomly among trials, thus preserving response magnitudes but eliminating any timing information. In that condition, there was a ~35% decrease in transmitted information. In the other condition, all spikes after the first spike were deleted, thus preserving first-spike latencies and the dispersion of first-spike latencies but eliminating information from spike counts. That resulted in a decrease in transmitted information of only ~11%. In tests of information transmitted by unidimensional terms, spike count or first-spike latency, latency transmitted significantly more information than did spike count.

Similar results pertaining to spike timing, and some differences, were obtained in area A1 of awake cats (Mickey, B. J. and Middlebrooks, J. C., 2003). Complete elimination of the stimulus dependence of spike timing reduced transmission of stimulus-related information by ~50%. The awake cat A1 results differed somewhat from the results from A2 in anesthetized cats in that a substantial decrease in transmitted information was evident in the awake A1 study only when spike times were degraded on a scale of greater than ~16 ms, whereas in the anesthetized A2 study (Furukawa, S. and Middlebrooks, J. C., 2002), a substantial decrease in transmitted information was observed for degradation of timing on a scale as fine as 4 ms. Also different from the A2 study, spike count alone on average transmitted more information than did first-spike latency alone. The result likely reflects the fact that response patterns tended to be more sustained in the awake condition than in the anesthetized condition, resulting in higher spike counts and greater potential for modulation of spike counts by sound-source location.

First-spike latency typically shows a strong negative correlation with spike counts. For that reason, the amount of information transmitted in area A2 by two-dimensional vectors of spike count and spike latency is substantially less than the sum of the information transmitted by either term alone (Furukawa, S. and Middlebrooks, J. C., 2002). Location-related variation of first-spike latency is appreciably greater in area PAF than in areas A1 and A2 (Stecker, G. C. *et al*., 2003). Correlation between spike count and first-spike latency is significantly weaker in PAF, suggesting that latency contributes a greater increment in transmitted information in PAF than is the case in A1 or A2.

Estimates of transmitted information that rely on first-spike latency require knowledge of the time of onset of the sound, which is not directly available to an animal. A more biologically plausible approach would be to examine stimulus-related information that could be carried by the relative timing of spikes among neurons. Stecker G. C. and Middlebrooks J. C. (2003) compared information transmitted by patterns of spikes timed relative to stimulus onset (absolute spike times) with information transmitted by patterns of spike-time differences between pairs of spikes. When pairs of neurons were selected both from area A1 or both from PAF, information transmission by relative spike times was reduced compared to the absolute-time condition, although the relative times did transmit appreciable amounts of information. In contrast, when pairs of neurons were formed by one A1 neuron and one PAF neuron, relative and absolute spike times transmitted roughly equal amounts of information. It appears that the somewhat restricted range of spike latencies in A1 served as an adequate temporal reference by which to measure the widely varying latencies in PAF. Additional studies of information transmission by relative spike times are considered in the context of location signaling by populations of neurons, discussed in the next section.

3.46.3.3 Location Signaling by Populations of Neurons

Despite the potential for single neurons to signal sound locations throughout auditory space, no single neuron can do so accurately enough to account for the accuracy observed in behavioral trials. Hypothetically, that additional accuracy could be gained from the coordinated activity of populations of neurons. That hypothesis has been explored with

classifiers that act on simple combinations of spike patterns of multiple neurons (Furukawa, S. *et al.*, 2000; Mickey, B. J. and Middlebrooks, J. C., 2003; Stecker, G. C. *et al.*, 2003) and with classifiers that exploit some particular differential response among neurons (Jenison, R. L., 1998; 2000; 2001; Stecker, G. C. and Middlebrooks, J. C., 2003; Stecker, G. C. *et al.*, 2005b).

Furukawa S. *et al.* (2000) explored azimuth signaling by ensembles of 2–128 neurons in area A2 of anesthetized cats. Neuronal single- and multiunit data were recorded from multisite recording probes that enabled simultaneous recordings at 16 sites spaced in 100 μm intervals (i.e., all recordings were along a 1500 μm oblique line through the cortex). Ensemble spike patterns were formed either by concatenating patterns of single neurons or by compiling multiple random samples of 1–128 neural units from a pool of 377 units. Ensemble spike patterns were classified using techniques like those described in Section 3.46.3.1. Relative spike timing and spike counts among neurons were preserved by that procedure, but there was no explicit procedure to differentiate timing or count among neurons. Localization signaling performance improved rapidly with increases in the size of ensembles from 1 to about 8 or 16, then improved more slowly beyond that size. An ensemble of 128 units produced localization performance comparable to cat localization behavior (May, B. J. and Huang, A. Y., 1996). It has been noted that a substantial fraction of stimulus-related information in spike patterns is carried by spike timing (discussed in Section 3.46.3.3). The study by Furukawa and colleagues demonstrated that a similar amount of information is carried by times measured relative to the onset of the stimulus or by times measured relative to the first spike across the ensemble of neurons.

Localization signaling performance in the study by Furukawa S. *et al.* (2000) was better when units were drawn from across all recording-probe locations in multiple animals than when all units were recorded with the same 16-site probe. That suggests that localization is enhanced by neural ensembles that exhibit a greater diversity in spatial sensitivity of single units. Neurons in area PAF of anesthetized cats (Stecker, G. C. *et al.*, 2003) and A1 in awake cats (Mickey, B. J. and Middlebrooks, J. C., 2003) show substantially greater diversity of spatial sensitivity and spike patterns than do neurons in areas A1 and A2 in anesthetized cats. Analysis of location signaling by neural ensembles using procedures similar to that introduced by Furukawa and colleagues showed enhanced growth of signaling accuracy associated with increasing ensemble size in area PAF in anesthetized cats (Stecker, G. C. *et al.*, 2003) and A1 in awake cats (Mickey, B. J. and Middlebrooks, J. C., 2003) compared to areas A1 and A2 in anesthetized cats.

As noted in Section 3.46.2.1, the first-spike latencies of cortical neurons typically vary with sound-source location. Jenison R. L. *et al.* (1998) explored location signaling by the first-spike latencies of ensembles of neurons in area A1 of anesthetized cats. The spatial sensitivity of the latency of each neuron was measured with virtual auditory space techniques, then that sensitivity was modeled using a form of spherical approximation with von Mises basis functions (as in Figure 2; Jenison, R. L. and Fissel, K., 1995; 1996). A maximum-likelihood estimator then was used to estimate sound-source locations based on modeled latencies from ensembles of neurons. Performance was quantified by Monte Carlo simulations and by analytic computation of the Cramer–Rao lower bound (CRLB; Blahut, R. E., 1987), which is a measure of the variance of an unbiased estimator. Neural ensembles of varying sizes were drawn from a population of 65 single neurons studied in area A1 of anesthetized cats (Brugge, J. F. *et al.*, 1996). Performance improved rapidly with increases in ensemble size up to about 20 neurons. Asymptotic values of localization error for targets at 0° azimuth and 0° elevation were comparable to psychophysical values reported in humans (Makous, J. C. and Middlebrooks, J. C., 1990) and cats (May, B. J. and Huang, A. Y., 1996).

Jenison has extended his work in several ways. First, he showed that very similar localization performance is obtained if latencies are expressed relative to the stimulus onset (absolute latencies) or are expressed relative to the first spike in the ensemble (relative ensemble latencies) (Jenison, R. L., 2001). That result is consistent with the results of Furukawa S. *et al.* (2000) obtained with a very different form of classifier. Second, he added a sound-level term to the radial-basis-function representations of spatial receptive fields (Reale, R. A. *et al.*, 2003). Localization performance initially improved with increasing sound level, consistent with human psychophysical results (Sabin, A. T. *et al.*, 2005). Further increases in level tended to result in decreases in performance, which is not seen psychophysically except for localization of transients in elevation (Hartmann, W. M. and Rakerd, B., 1993; Macpherson, E. A. and Middlebrooks, J. C., 2000).

Finally, he demonstrated the interesting and rather unexpected result that localization by the first-spike latencies of an ensemble of neurons is enhanced by correlation among the individual neurons (Jenison, R. L., 2000).

3.46.3.4 An Opponent Process Model

Stecker G. C. *et al.* (2005b) have evaluated an opponent-process model of spatial representation. That model is based on the observation that auditory space is sampled quite nonhomogeneously by receptive fields. Indeed, as noted in Section 3.46.2, the spatial receptive fields of the large majority of neurons are centered on the acoustic axis of one or the other pinna, and few receptive fields are centered on the midline. The tendency of receptive fields to lie off the midline means that the steepest spatial gradients of neurons' spike counts or latencies tend to lie on or near the midline. The near-midline locations of steep response gradients are reflected in the tendency of spike-pattern classifiers (as in Section 3.46.3.1) to discriminate left from right with great acuity while often failing to discriminate locations within one or the other sound hemifield (e.g., see Figure 4, right column). Moreover, specific tests of the discrimination of pairs of locations by neurons in areas A1, PAF, and DZ of anesthetized cats showed that the greatest spatial acuity was for pairs of locations that straddled the frontal midline.

The opponent process model asserts that sound-source locations could be represented by the relative activity of a small number of discrete populations of neurons, as small as two, each population defined by tuning to a particular region of space. Inasmuch as the majority of neurons in each cerebral hemisphere are tuned to locations in the contralateral frontal quadrant, one might think first of a comparison of activity between left and right hemispheres. That notion is untenable, however, because it predicts that a unilateral lesion would produce a bilateral localization deficit, contrary to the largely contralateral deficits that are observed (see Section 3.46.4). Instead, Stecker G. C. *et al.* (2005b) argue that an opponent process localizer could be constituted from contralaterally tuned and the relatively few ipsilaterally tuned neurons within each hemisphere; ipsilaterally tuned neurons are particularly prevalent in area DZ (Stecker, G. C. *et al.*, 2005a). As a proof of concept, they tested a simplified model that summed normalized spike counts from contralaterally tuned neurons and subtracted them from summed counts from ipsilaterally tuned neurons. Classification of those difference terms provided localization performance that was clearly superior to classification of simple summed spike counts, particularly in conditions of varying sound levels. That test dealt only with overall levels of activation among two populations. One assumes that performance could only be better if the complexity of interconnections among neurons were to be exploited in a more realistic manner.

The opponent process model may be regarded as an extension of the panoramic coding described in Section 3.46.3.1. Results presented in that section indicate that spike patterns of many neurons can signal the locations of sound sources throughout as much as 360° of space. The opponent process model simply points out what is clear in most of the cited publications, that most of those neurons discriminate near-midline locations more accurately than they discriminate locations far off the midline. We note that the enhanced discrimination of midline locations by neurons fits with psychophysical evidence that spatial discrimination is most acute (Mills, A. W., 1958) and that localization is most accurate (Makous, J. C. and Middlebrooks, J. C., 1990; Stevens, S. S. and Newman, E. B., 1936; May, B. J. and Huang, A. Y., 1996) for near-midline targets. Furukawa S. *et al.* (2000) demonstrated that ensembles of panoramic neurons signal sound locations more accurately than do single neurons. The opponent process model extends that observation by suggesting a particular way in which information might be combined across populations – that is, as a differential between populations tuned to left or right hemifields.

3.46.4 Impact of Cortical Inactivation on Localization Behavior

The ability to localize sounds in space has long been known to depend on intact auditory cortex (e.g., Neff, W. D. *et al.*, 1956). In general, the removal or inactivation of auditory cortex in one hemisphere renders animals unable to approach, or even discriminate, the locations of sound sources in the contralateral hemifield, whereas localization performance in the ipsilateral hemifield is largely unaffected (e.g., Jenkins, W. M. and Masterton, R. B., 1982; Thompson, G. C. and Cortez, A. M., 1983; Heffner, H. E., 1997). When the auditory cortex is removed or inactivated bilaterally, the animals are rendered

unable to approach or discriminate sound sources within either lateral hemifield but generally can discriminate whether a sound source is located on the left or right, albeit with reduced acuity (Heffner, H. E. and Masterton, B., 1975; Heffner, H., 1978; Heffner, H. E. and Heffner, R. S., 1990). In what follows, we will review some of the effects of cortical lesions, as well as acute and chronic cortical inactivation, on the sound-localization behavior of species including cats, ferrets, dogs, and monkeys. It should be emphasized that although the effects of cortical lesions are similar among these species, they cannot be generalized to all species.

3.46.4.1 Role of the Auditory Cortex in Reflexive Orientation to Sound Sources

Not long after the auditory cortex was first implicated in the operant auditory spatial behavior of the cat (Neff, W. D. *et al.*, 1956; see Section 3.46.4.2), researchers began to address its role in reflexive orientation to sound sources. In the first of these studies, Riss W. (1959) observed the orienting responses of cats with bilateral auditory cortex lesions and concluded that the auditory cortex was necessary for "localizing the instantaneous position of a sound source," even when the ability was assessed in terms of reflexive orientation. Indeed, when the animals were deprived of all visual cues, their orienting responses were unrelated to the actual location of the sound source. In contrast, several later studies concluded that while the orienting responses of cats with large bilateral lesions were often abnormal, they were not entirely absent (Thompson, R. F. and Welker, W. I., 1963; Thompson, G. C. and Masterton, R. B., 1978; Beitel, R. E. and Kaas, J. H., 1993). Specifically, although most responses were generally toward the appropriate lateral hemifield, the accuracy of the final head position within that hemifield was often diminished. Indeed, in the study by Beitel and Kaas, the position of the animal's head following an orienting response was unrelated to the position of the sound source, beyond being within the appropriate hemifield. However, Thompson G. C. and Masterton R. B. (1978) observed that when the initial direction of a head turn was appropriate (e.g., turning left for a leftward source), so too was the remainder of the response. The fact that orienting responses could appear normal on one trial and aberrant on the next led those authors to suggest that the systems involved in reflexive responses to sound, although not cortical *per se*, might be under cortical control (Thompson, G. C. and Masterton, R. B., 1978). These results suggest that while bilateral lesions might impair the ability of cats to accurately orient to sound sources within a lateral hemifield, they have only a slight effect on the ability to orient appropriately to the left or the right side of the midline.

3.46.4.2 Role of the Auditory Cortex in Operant Localization of Sound Sources

In the earliest lesion study of sound localization, bilateral auditory cortex lesions impaired the ability of cats to approach a target on the left or right when it was identified by an auditory, but not a visual, cue (Neff, W. D. *et al.*, 1956). Despite their impairment, however, cats were often able to perform the task above chance levels when just two targets were used, located close to the animal on the left and right. A similar observation was later made in dogs (Heffner, H. E., 1978). Neff proposed that the deficit might reflect an inability to maintain attention between the initiation and completion of an operant response. When the target was closer to the animals, the attentional demands of the task were reduced, and performance improved. Whatever its explanation, the demonstration of an auditory localization deficit, however incomplete, supported the involvement of auditory cortex in sound-localization behavior.

Following the study by Neff W. D. *et al.* (1956), Strominger N. L. (1969a; 1969b) provided additional evidence for the preservation of left–right discrimination following bilateral lesions in cats, as well as the first evidence for an impairment following unilateral lesions (Strominger, N. L., 1969b). Cats were again trained to approach targets on the left and right. Following unilateral lesions, although some animals expressed a bias toward targets on the same side as their lesion (i.e., opposite their intact hemisphere), their behavior was otherwise unremarkable. Following bilateral lesions, however, the animals were unable to perform the discrimination except at the largest separation of 180° (Strominger, N. L., 1969b). Later studies of monkeys, dogs, and ferrets also demonstrated that while the ability to perform left–right discriminations persists following bilateral lesions, the animals' spatial resolution often was deficient and, at least in monkeys, that the degree of deficiency may be task dependent (Heffner, H. E. and Masterton, B., 1975; Heffner, H. E., 1978; Kavanagh, G. L. and Kelly, J. B., 1987; Heffner, H. E.

and Heffner, R. S., 1990). Indeed, the observation that monkeys with bilateral lesions were able to indicate whether a sound came from the left or right by making a corresponding (left or right) lever press, but not by approaching the source of the sound led to the suggestion that, "... what auditory cortex lesions seem to produce ... is an inability to demonstrate sound localization in some tasks" (Heffner, H. E. and Masterton, B., 1975; 1978, p. 742).

These and other studies suggested that cortical lesions impair but do not eliminate the ability of cats, dogs, ferrets, and monkeys to reflexively orient toward, identify, or discriminate sound sources between the left and right hemifields. It was only when animals began to be tested for the ability to localize sound sources within a lateral hemifield, however, that the severity of sound-localization deficits, particularly those that follow unilateral lesions, was made apparent. Jenkins W. M. and Masterton R. B. (1982) required cats to walk to a sound source within an array of speakers spanning 180°, a task that normal animals performed well. Following unilateral lesions, however, the accuracy of their responses was profoundly diminished in the contralesional, but not the ipsilesional, hemifield. This test procedure was later used to demonstrate contralesional deficits of tone localization that were limited to frequencies whose cortical representation in the primary field (A1) had been removed (Jenkins, W. M. and Merzenich, M. M., 1984), as well as a contralesional localization deficit in squirrel monkeys (Thompson, G. C. and Cortez, A. M., 1983). Interestingly, as with the cats tested by Strominger N. L. (1969a), when presented with a contralesional sound source, the squirrel monkeys often responded to ipsilesional sources (Thompson, G. C. and Cortez, A. M., 1983). Subsequent studies have demonstrated that monkeys and ferrets are not only unable to approach contralesional sound sources accurately, they are unable to discriminate them using simpler operant procedures (Kavanagh, G. L. and Kelly, J. B., 1987; Heffner, H. E. and Heffner, R. S., 1990).

Although each hemisphere is primarily responsible for spatial behavior in the contralateral hemifield, regions of space near the midline appear to be represented bilaterally. This ipsilateral spillover is evident when the spatial deficits that follow unilateral lesions in monkeys are mapped by fixing the location of one sound source and systematically varying the location of another sound source in a discrimination task (Heffner, H. E. and Heffner, R. S., 1990; Heffner, H. E., 1997). When both sound sources are more than 15–30° into the contralesional hemifield, they can no longer be discriminated regardless of how widely they are separated within that hemifield. In cases of bilateral lesions, discrimination fails as soon as the two sources are on the same side of the midline, again regardless of their separation (Heffner, H. E. and Heffner, R. S., 1990; Heffner, H. E., 1997). This suggests that each cerebral hemisphere represents the entire contralateral hemifield in addition to the 15–30° of the ipsilateral hemifield closest to the interaural midline. In the absence of auditory cortex in both hemispheres, the animals are only able to distinguish sounds on the left from those on the right. It is possible, however, that the animals might be performing this left–right discrimination on the basis of nonspatial cues. That is, although dogs and monkeys can learn to approach a left and right sound source with persistent training, their ability to rapidly transfer this spatial response to the discrimination of nonspatial stimulus features suggests that they may be making a spatial response to what is for them a nonspatial stimulus (Heffner, H. E., 1978).

3.46.4.3 Reversible Cortical Inactivation

Reversible inactivation techniques have emerged as a powerful tool for the investigation of brain–behavior relationships and have been used to study the role of auditory cortex in sound-localization behavior (Malhotra, S. *et al.*, 2004; Smith, A. L. *et al.*, 2004; Malhotra, S. *et al.*, 2005; Malhotra, S. and Lomber, S. G., 2007). One obvious advantage of these techniques is that the inactivation is fast-acting and reversible and thus should not lead to plastic reorganization (at least when used in the short term). They also allow for the immediate assessment of behavior during the inactivation, in contrast to lesion studies in which a period of postoperative recovery is often necessary, and allow the same experimental animals to be tested repeatedly in their normal and inactivated state (Lomber, S. G., 1999). Malhotra S. *et al.* (2004) have used cryogenic deactivation to study the involvement of individual auditory cortical fields in the localization behavior of the cat. The animals were trained to approach sound sources before, during, and after the unilateral inactivation of individual cortical fields. Of all the areas tested, only inactivation of areas A1, PAF, and AES resulted in auditory-specific localization deficits; the inactivation of two motor areas, 5L and 6m, produced modality-nonspecific deficits (Malhotra, S. *et al.*, 2004). Consistent with the effects of cortical lesions, deficits were restricted to the contralateral hemifield during

unilateral deactivations of A1, PAF, or AES (Malhotra, S. *et al.*, 2004) and were present in both hemifields during bilateral inactivations of A1, PAF, or AES (Malhotra, S. and Lomber, S. G., 2007). The latter deficits were observed following either homotopic (e.g., A1 on both sides) or heterotopic (e.g., A1 on the left and PAF on the right) inactivation. Despite their inability to accurately approach sound sources, the animals generally were able to orient toward the appropriate lateral hemifield, a finding consistent with lesion studies (e.g., Beitel, R. E. and Kaas, J. H., 1993). Thus, the deficits that occur during acute unilateral and bilateral inactivations of auditory cortex are similar to those that follow cortical lesions. It remains to be seen, however, whether the same inactivations would also impair the discrimination of sound-source locations.

Physiological results suggest that areas PAF and DZ might have particular importance for localization behavior (see Section 3.46.2.2). The expectation regarding PAF is supported by the reversible inactivation results (Malhotra, S. *et al.*, 2004). The inactivation of area A1 by Malhotra and colleagues did not distinguish the main (ventral) portion of A1 from DZ. Ongoing studies suggest that inactivation of ventral A1 alone increases the proportion of incorrect responses, whereas inactivation of DZ results in an increase in the number of very large errors (Malhotra, S. *et al.*, 2005). Physiological results do not predict the localization deficits resulting from AES inactivation in that AES neurons do not show especially strong spatial sensitivity. Those localization deficits might reflect in some way the projection from AES to the superior colliculus (Meredith, M. A. and Clemo, H. R., 1989).

Smith A. L. *et al.* (2004) have determined the effects of the longer-term chemical inactivations on the sound-localization behavior of ferrets. The animals were trained to walk to the source of a sound in a circular arena and then received unilateral or bilateral, slow-release implants over A1 that had been impregnated with the GABA agonist, muscimol. These implants produce tonic inhibition of neural activity in their immediate vicinity and can remain effective for up to 5 months. Although the animals with bilateral inactivations showed substantially decreased localization accuracy, particularly for shorter stimulus durations, their deficits were not complete and diminished with further testing. Again consistent with the contralateral control of spatial behavior evidenced by lesion and cryogenic inactivation studies (e.g., Jenkins, W. M. and Masterton, R. B., 1982; Kavanagh, G. L. and Kelly, J. B., 1987; Malhotra, S. *et al.*, 2004), animals with unilateral inactivations made larger errors in the contralateral hemifield (Smith, A. L. *et al.*, 2004). There was also a marked tendency for animals to make more front/back confusions following the bilateral inactivation of A1, leading to the suggestion that A1 may be involved in the resolution of the spectral cues that distinguish to the front/back locations of sound sources. It should be noted, however, that the accuracy of the initial head-orienting response to sound source was not affected by the chemical inactivation of A1. Indeed, the animals' initial orienting responses were not only toward the appropriate lateral hemifield but within 30° of the target, suggesting a disconnection between spatial information and certain operant spatial behaviors.

3.46.4.4 Summary of Effects of Cortical Inactivation

The auditory cortex plays a critical role in the sound-localization behavior of cats, dogs, ferrets, and monkeys (e.g., Neff, W. D. *et al.*, 1956; Heffner, H. E., 1978; Kavanagh, G. L. and Kelly, J. B., 1987; Heffner, H. E. and Heffner, R. S., 1990). Although the ability to perform left–right discriminations persists following bilateral lesions, the animals tend to have reduced spatial acuity (as evidenced by increased discrimination thresholds) and may in fact be performing what is for them a quasispatial task (Heffner, H. E., 1978; Heffner, H. E. and Heffner, R. S., 1990). In operant localization tasks, for example, the animals might simply be reinforced for trusting their reflexes, as these reflexes appear entirely sufficient to indicate the hemifield from which a sound originated (Beitel, R. E. and Kaas, J. H., 1993), or they might learn to associate location-dependent stimulus variations with appropriate behavioral responses (Heffner, H. E. and Heffner, R. S., 1990). This might also account for the observation that the left–right discrimination performance of cats and dogs is improved when the target is closer to the initial position of the animal (Neff, W. D. *et al.*, 1956; Heffner, H. E., 1978) – the proximity decreases the likelihood of the animal second-guessing its reflex. Neither of these strategies would require the animal to retain a normal appreciation of left or right or any other spatial quality for that matter. Within a lateral hemifield, however, the animals are completely unable to identify the location of a sound source, regardless of whether the ability is assessed using operant or reflexive methods
